Fig. 14.26 (Left) The electron density distribution of bromine atoms in the unit cell. (Right) The electron density distribution of the di18:0(9,10Br)PC and cholesterol mixture. The high density regions are phosphate headgroups and bromine atoms (Wang *et al.*, 2007).

the association energies between lipid molecules vary with the curvature of membrane. Thus lipid components in a mixture may redistribute under conditions of nonuniform curvature, for example during membrane fusion. In such cases, the spontaneous curvature depends on the local lipid composition and the free energy minimum is determined by lipid distribution as well as curvature.

Example 3: Rhombohedral Phase The MAD method was also applied to a rhombohedral phase. Alamethicin is a well- known antimicrobial peptide. The peptide is known to form pores in membranes by ion conduction (Hall *et al.*, 1984), neutron scattering (He *et al.*, 1995; He *et al.*, 1996), and oriented circular dichroism (Huang and Wu, 1991) experiments, but its pore structure has never been observed. Thus our goal was to use the MAD method to directly observe the pore structure in membrane (Qian *et al.*, 2008).

We first examined alamethicin and di18:0(9,10Br)PC mixtures in full hydration. Using the method of oriented circular dichroism (Wu *et al.*, 1990; He

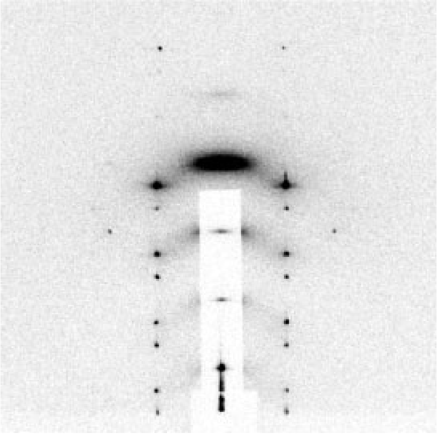

Fig. 14.27 Diffraction patterns of alamethicin/di18:0(9.10Br)PC $P/L = 1:20$ at 40% < RH < 55%, 25 °C. The patterns are of rhombohedral symmetry (space group $R\bar{3}$). The dimensions of the unit cells are $c = 4.95$ nm, $a = 5.94$ nm (the same notation as in Section 14.5.2.1) (Qian *et al.*, 2008).

et al., 1995, 1996), we found that alamethicin formed pores in the lipid bilayers if its concentration exceeded 1 : 30 peptide–lipid molar ratio. When such mixtures were dehydrated below 55% RH at 25 °C, the system transformed from the lamellar phase to the rhombohedral (R) phase.

The diffraction pattern of the R phase is shown in Figure 14.27 and the MAD analysis is shown in Figure 14.28. The phase problem was solved by fitting a model to the Br distribution. The experimental electron density of the lipid–alamethicin mixture shows a barrel-stave type of pore (Figure 14.29).

For the first time a peptide-induced pore in membrane is directly imaged by reconstructing its electron density based on X-ray diffraction. Because the

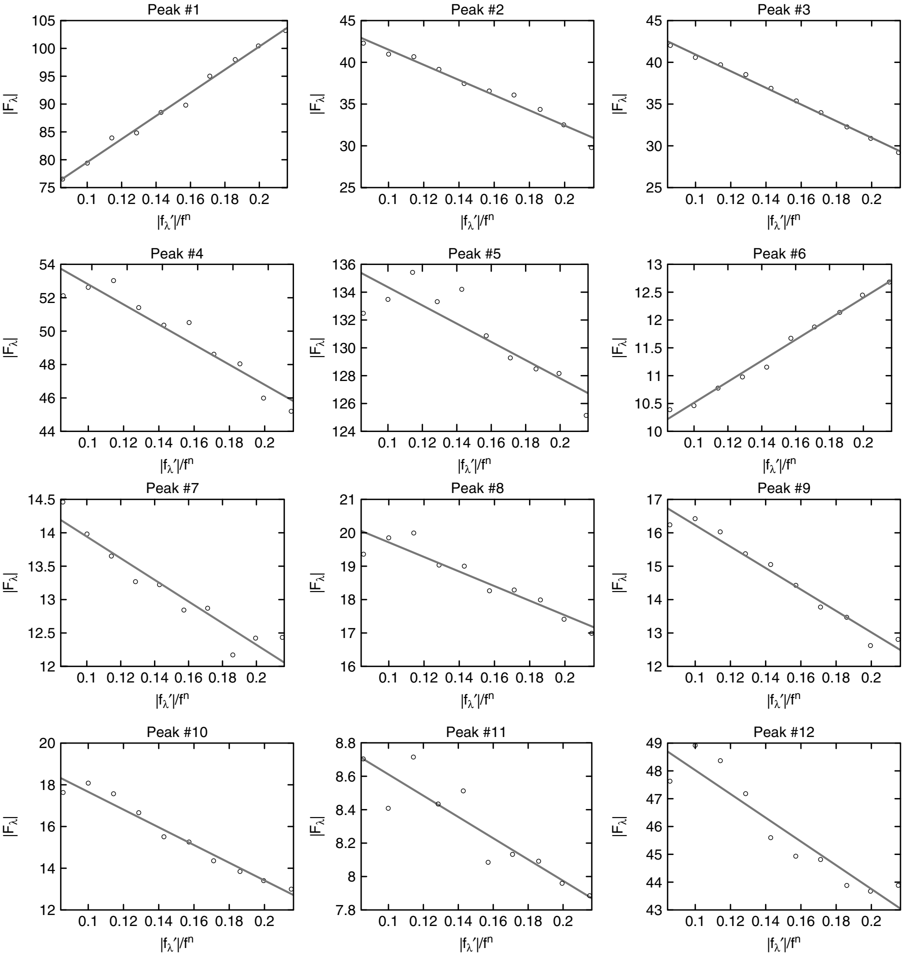

Fig. 14.28 MAD analyses for the detected peaks in Figure 14.27. For each independent peak, the square-root of the integrated intensity, $|F_\lambda|$, is plotted as a function of $|f'_\lambda|/f^n$. The data are fit with a straight line, from which $|F_0|$, $|F_2|$, and the ratio F_0/F_2 are obtained (Qian *et al.*, 2008).

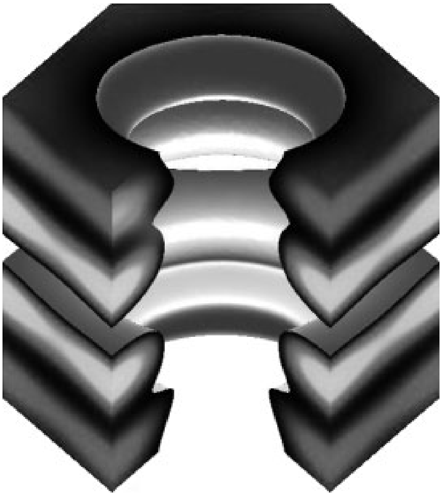

Fig. 14.29 Three dimensional view of a unit cell. One-sixth of the unit cell is removed to show the interior. The surface of electron density distribution is chosen at a density value such that the central hole has a radius 2.0 nm, according to the model. The low-resolution diffraction essentially reveals the layers of phosphate groups (top and bottom layers) and the layers of bromine atoms (the two interior layers). An alamethicin channel of eight monomers arranged in the barrel-stave fashion fits the hole perfectly (Qian *et al.*, 2008).

molecular assembly of the pore is defined by the atomic distribution rather than by atomic positions, and also because soft-matter structures have a high intrinsic disorder, its diffraction pattern is limited to relatively small q values. Only the high density parts are clearly revealed by the low-resolution diffraction. The clearly visible regions include the distribution of phosphate groups of the lipids and the distribution of the heavy atoms bromines that are bound to carbon 9 and 10 of each hydrocarbon chain. Unfortunately the peptide alamethicin does not possess high electron density; therefore their positions are not visible. Nevertheless, the lipid assembly is unambiguously defined by the distributions of the phosphate group and the bromines bound to carbons 9 and 10. The lipid assembly for the alamethicin pore is unmistakably that of a barrel-stave construction. This lipid assembly accommodates a channel made of n alamethicin helixes. From the crystallographic data (Fox and Richards, 1982), we know that an alamethicin monomer is a cylinder of 3.2 nm long and 1.1 nm in diameter. A channel of eight alamethicin helices gives an outside radius of 1.95 nm that fits the lipid assembly perfectly.

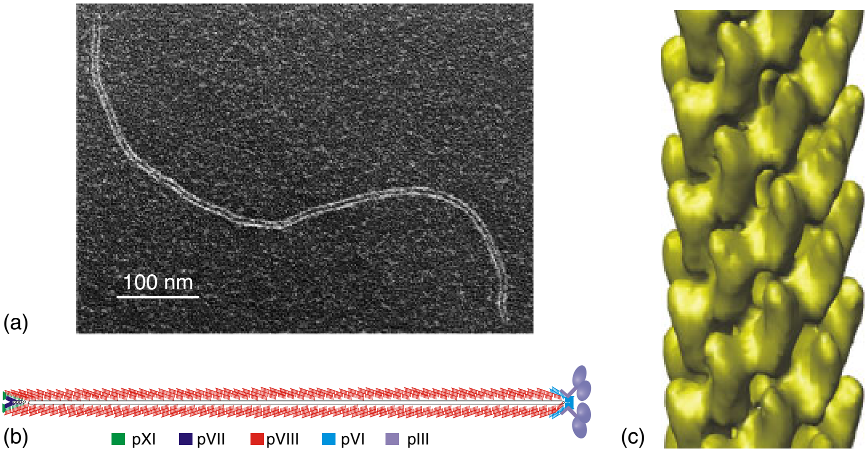

Fig. 13.10 The filamentous ssDNA bacteriophage fd. (a) A negatively stained electron micrograph showing one complete virion. The flexibility of the virion, which is apparent, is consistent with the experimentally determined equilibrium persistence length of 1.0 µm. (b) Cartoon of fd (not to scale) showing locations of the minor coat proteins. (c) Reconstruction of a 24 nm segment of fd at ~8 Å resolution from images obtained by electron cryomicroscopy (courtesy of E. H. Egelman, University of Virginia). (This figure also appears on page 444.)

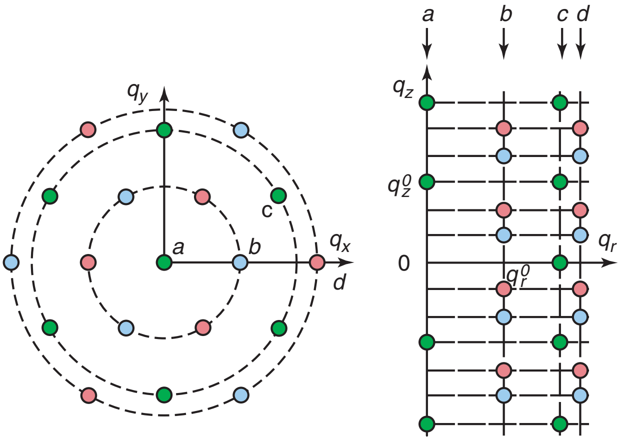

Fig. 14.17 The reciprocal lattice of rhombohedral symmetry on the $q_x - q_y$ plane (left) and the diffraction peaks detected on the $q_z - q_r$ plane (right). The reciprocal lattice of rhombohedral symmetry is composed of a stack of hexagonal layers stacked up in the ABCABC... sequence (A green, B blue, C red). In the $q_z - q_r$ plane are the four columns of the observed diffraction peaks. In Figure 14.18, the swelling method was applied to each set of the peaks having the same (H, K) (same color): column $a(H = 0, K = 0)$, $b(1, 0)$, $c(1, 1)$, and $d(2,0)$. The set of red peaks and the set of blue peaks in each of column b and d are equivalent by centrosymmetry (Yang and Huang, 2003). (This figure also appears on page 485.)

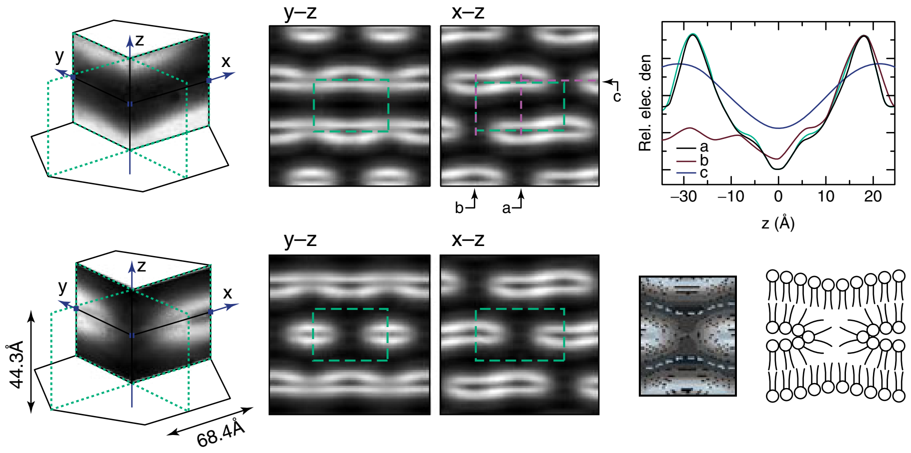

Fig. 14.19 Electron density distribution in the unit cell of the rhombohedral lattice (High density is white, low density is black.) (Top row): The unit cell was based on the phases determined by the swelling and pattern recognition methods. The stalk structure is not obvious in this unit cell. To its right are the density maps in the $y - z$ and $x - z$ planes. The dashed green rectangles are the boundaries of the unit cell in each map. On the $x - z$ map, the electron density profiles were taken along three lines a, b, and c, and shown in the top right panel. Also shown in the panel is a trans-bilayer density profile from the L_α phase. The bilayer portion in the rhombohedral phase remained very close to the L_α phase. (Bottom row): The unit cell was obtained by a translation from the previous one. A stalk structure appeared at the center of the cell. The maps on the $y - z$ and $x - z$ planes are shown to its right. The central part of the $y - z$ map is re-plotted with density contours on the right hand side, along with a cartoon of a talk where two lipid monolayers merged to form a hourglass structure (Yang and Huang, 2003). (This figure also appears on page 487.)

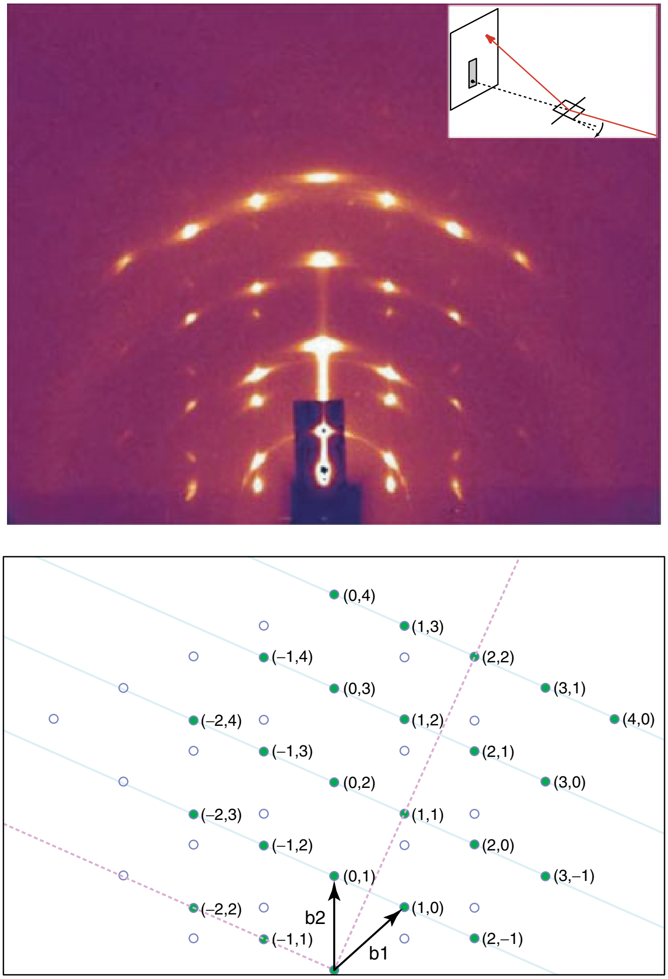

Fig. 14.24 (Top) The detector image of X-ray reflection from a 2 : 1 mixture of di18:0(9,10Br)PC and cholesterol in the $H_{II\delta}$ phase. The inset shows a schematic of the diffraction geometry. (Bottom) The diffraction pattern was translated to the reciprocal space according to the diffraction geometry. The two reciprocal vectors are $\mathbf{b}_1 = (0.1314\text{Å}^{-1} \sin 48.2^\circ, 0.1314\ \text{Å}^{-1} \cos 48.2^\circ)$ and $\mathbf{b}_2 = (0, 0.1314\ \text{Å}^{-1})$, expressed in (q_x, q_z). The angle between the two basis reciprocal vectors is 48.2°, which substantially deviates from the hexagonal angle of 60°. The solid green dots are the lattice defined by $\mathbf{b}_1$ and $\mathbf{b}_2$. The open circles are the mirror image of the lattice reflected by the mirror plane along the q_z and perpendicular to q_x – this left–right symmetry is due to the sample being a 2D powder on the plane of the substrate. Owing to the equality $|\mathbf{b}_1| = |\mathbf{b}_2|$, there are two mirror planes (purple lines) in the crystal lattice, one bisecting $\mathbf{b}_1$ and $\mathbf{b}_2$, another bisecting $-\mathbf{b}_1$ and $\mathbf{b}_2$ (Wang *et al.*, 2007). (This figure also appears on page 494.)

15.1
Introduction

A review is given on the usage of microwave technology in biomolecular physics. This mainly concerns the rotational spectroscopy of small organic molecules, since relevant frequencies are in the microwave region, that is, 0.5–1000 GHz. Many applications can be found on microwave spectroscopy, such as air-pollution measurements, molecular investigations in astrophysics, conformational assessments of small molecules, and investigations of quantum-dot molecules (Townes and Schawlow, 1975; Kroto, 1992; Balle and Flygare, 1981; Arunan and Gutowsky, 1993; Emilsson, 1993; Rotational Micro-Wave Spectra, 2008; Larhed and Hallberg, 2001; Dutton, 2002).

Later an analysis is presented on the topological structure of protein backbones with a focus on the differential geometrical aspect of winding and torsion of the peptide chain. By a careful study of the three-dimensional crystallographic coordinates of the backbone atoms for known proteins, the geometrical analysis provides profiles of local winding as well as global twists throughout the protein backbones. From such studies, physical, material science implications are derived for the early stages of protein folding in which ribosome-driven processes and processes where cyclosylation and signal peptides take part, are important. The physical phenomena of such processes include long range excitations of twistons and thermally driven transitions that are part of a topological phase diagram description. Interesting applications for possible protein folding experiments are discussed. The analysis is carried out for specific proteins where clear conclusions are being derived (Bohr and Bohr, 2000a,b; Lax and Button, 1962).

15.2
Introduction to Microwave Technology

In the second half of last century, after the Second World War, electromagnetic radiation in the microwave region of 0.5–1000 GHz has not only been used as a tool for, primarily, detection of molecular structures in chemical research (Arunan and Gutowsky, 1993; Emilsson *et al.*, 2000) but also as a tool for enhancement of chemical reaction kinetics (Bohr and Bohr, 2000a; Larhed and Hallberg, 2001; Dutton, 2002). The reason was first of all the availability

Handbook of Molecular Biophysics. Methods and Applications. Edited by Henrik G. Bohr.

ISBN: 978-3-527-40702-6

of microwave generators due to the invention of the magnetron that provided a cheap and effective way of generating microwaves of a few gigahertz corresponding to a wavelength of around 10 cm. $\nu = 1\ \text{GHz} \sim \lambda = 30$ cm in air. Thus, with the magnetron more precise radar detection was possible. Later the efficient magnetron found its way into the kitchen household as a cooking device for food. This was due to the fact that the magnetron, generating microwaves at 2.24 GHz, could quickly cook food with a large percentage of water and with a penetration depth of about 3 cm. The reason for this rapid heating was due to rotation of water dielectricum or (alternatively explained) a lining of dipoles according to the E-field oscillation with a peak at around 22 GHz. Micro-wave radiation generated at about 2 GHz would still be in the large tail of the water absorption peak and with a reasonable penetration depth that otherwise would be small right at the peak of absorption. The fact that rotational modes of small molecules could be stimulated by microwaves later became a possible tool for investigating atomic structure of molecules as described below. However, the drawback for MW as means of detection required ultra high vacuum for molecules in the gas phase.

15.3
Rotational Spectroscopy of Molecules

It is well known that electronic dynamics is quantized when electrons are bound to nuclei in the atoms. The quantization of the dynamics of the electron binding results in electrons being confined to distinct orbitals around the nucleus.

Similarly, rotational dynamics is quantized – a fact that is relevant especially to spherically asymmetric molecules and also actually to a spherical nuclei. Hence, the rotational energy and the angular momentum can only take specific, distinct values. This chapter reviews the rotational quantization and the corresponding spectroscopy of molecules. The fact that spherical asymmetry plays a big role in the quantization of rotational degrees of freedom can be seen in the dependance of moment of inertia in energy of rotation. Thus, electromagnetic radiation can change the quantum states, the rotational energy states of a molecule and certainly also give information of the molecular structure, for example, in terms of moments of inertia, by observing the absorption in rotational spectroscopy.

Below in Figure 15.1 is shown a typical experimental rotational spectrum of the HCl molecule in the gas phase (Rotational Micro-Wave Spectra, 2008). The spectrum exhibits a slight asymmetry corresponding to the asymmetry of the molecular structure due to the difference in mass of H and Cl. Along the vertical axis is intensity of absorption and horizontal line represents the wavelength.

The structure of these rotating molecules is importantly given, as mentioned above, by moments of inertia. Any molecule in three dimensions will in general have three moments of inertia: I_A, I_B, I_C about three mutually orthogonal axes: A, B, C and with an origin being the center of mass of the molecular system.

Some cases of symmetry are topically described by these three moments. For example, linear molecules with cylindrical symmetry will have negligible moments of inertia along the rotational axis

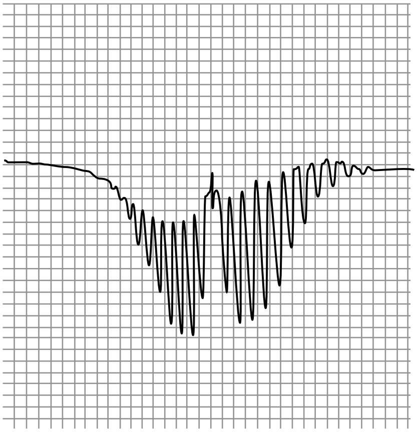

Fig. 15.1 A rotational spectrum of an HCl molecule in the gas phase (Rotational Micro-Wave Spectra, 2008).

A and therefore have ($I_A \ll I_B = I_C$). Thus the molecules' rotational behavior can be used to classify molecular structure and conveniently one can use four structural classes (Townes and Schawlow, 1975; Kroto, 1992) described below in subsections:

15.3.1
Linear Molecules

Here, one of the moments of inertia is negligible, for example, $I_A \ll I_B = I_C$. Often one sets $I_A = 0$. Therefore, the line separation in the rotational spectra can be uniquely related to the linear extension of the molecule. One of the most prominent cases of linear molecules are diatomic molecules such as, for example, H_2, O_2, $O \equiv C$ and also acetylene $HC \equiv CH$.

In order to interpret the rotational spectra, we have to specify the rotational energy levels. The energy, $E(J)$, for the linear molecules (rigid rotors) are quantized with a rotational quantum number, J, as:

$$E(J) = K_r J(J+1), \quad J = 0, 1, 2, \ldots \tag{1}$$

where K_r is a rotational constant of the molecule and related to the moments of inertia ($I_B = I_C$) by

$$K_r = \frac{h}{8\pi c I_B} \tag{2}$$

and with selection rules $\Delta J = J^1 - J^2 = \pm 1$ during absorption or emission. The transition lines in the rotational spectrum are spaced equally in wave numbers. Figure 15.1 shows transitions between the energy levels in a schematic spectrum of a linear molecule (Kroto, 1992).

15.3.2
Symmetric Tops

These molecular structures are generalization of the first case in the sense that they have two equal moments of inertia but a third one not negligible, for example, $I_A = I_B < I_C$. The symmetric tops are again divided into two classes: oblate symmetric tops (disc shaped) like above with $I_A = I_B < I_C$ and prolate symmetric tops (cigar shaped), with $I_A < I_B = I_C$. Here again, the spectra are very recognizable and bonding geometry can be deduced from those. Examples are benzene (oblate) C_6H_6 and chloroform (prolate) $CHCl_3$.

In the case of the symmetric top, one needs two independent rotational quantum numbers J, K to describe the energy, $E(J)$. The quantum numbers J, K correspond to rotations around the two independent axes B, A (prolate) or C (oblate). Actually, the number J is here associated with the total angular momentum and K is the number corresponding to the axis with different moment of inertia either in the oblate or the prolate case. The rotational energy is then in quantized form:

$$E(J, K) = K_r^1 J(J+1) + (K_r^2 - K_r^1)K^2 \tag{3}$$

with $J = 0, 1, 2, \ldots$ and $K = -J, -J+1, \ldots, -1, 0, 1, \ldots, J-1, J$ and where $K_r^1 = (h/8\pi c I_B)$ and $K_r^2 = (h/8\pi c I_C)$ (oblate) or $K_r^2 = (h/8\pi c I_A)$ (prolate) are the rotational constants of the molecule related to the moments of inertia I_B, I_C, or I_A.

The selection rules are in this case $\Delta J = \pm 1$ and $\Delta K = 0$ during absorption or emission. The reason for $\Delta K = 0$ is because the molecule is symmetric around the corresponding axis and therefore has no resulting dipole moment along that axis. In the rotational spectrum, one observes the same lines as in the case of linear molecules but with an extra "dimension" in the rotational spectrum and again with lines spaced equally in wave numbers (Rotational Micro-Wave Spectra, 2008).

15.3.3
Spherical Tops

This case, being a special case of 2, has all moments of inertia equal $I_A = I_B = I_C$. Thus, there are no specific spectral characteristics. Examples of that molecules are carbon tetrachloride CCl_4 and phosphorus tetramer P_4.

15.3.4
Asymmetric Tops

In this case, all moments of inertia are different. Most molecules will have such an asymmetrical structure and spectroscopically there will be no clear patterns in the spectra. It is, however, possible that the molecule can be divided into substructures that each satisfies one of the above symmetries and in that case one can still read out structural properties of the spectra. On the other hand, smaller molecules can form larger aggregates thereby making a structural deduction from the spectra very difficult. This is the case with, for instance, water. Examples of asymmetric tops are nitrogen dioxide NO_2, water H_2O and nucleic acids or amino acids.

15.3.5
Rotational Spectra of Small Molecules from Microwave Experiments

Very elaborate experimental constructions have been made for determining the rotational spectra and hence the accurate structures of smaller molecules in the gas phase. This involves large apparatus, often cylindrical containers maintaining the sample molecule in ultra high vacuum irradiated with microwaves at different frequencies around a few gigahertz (Balle and Flygare, 1981). The fact that rotational spectra can be recorded for, for example, organic molecules makes it possible to derive parts of the structural data about the molecule. For example, it is possible to distinguish between linearly extended molecules and symmetric tops according to the paragraphs mentioned above. For the main class of asymmetric tops a large number of structural data can be derived with the help of computer algorithms. Therefore, a large amount of research has been produced in the area of structural chemistry (Arunan and Gutowsky, 1993; Emilsson *et al.*, 2000). Such methods are, however, hard to carry out for large biomolecules.

One apparatus for detecting the rotational states of smaller molecules in the gas phase has been the pulsed nozzle Fourier transform microwave spectrometer developed 30 years ago (Balle and Flygare, 1981) but improved by Gutowsky and coworkers (Arunan and Gutowsky, 1993; Emilsson *et al.*, 2000). The apparatus has been especially useful for locating the hydrogen atoms in molecules and complexes due to the sensitive detection of small hyperfine interactions via the quadrupole couplings and spin–spin interactions. Figure 15.2 shows the rotational spectra of *benzene* – $C_6H_6 + H_2O$.

15.4 Microwave Absorption by Protein Molecules

The complex process of protein folding has many interesting facets (Anfinsen and Scheraga, 1975; Dobson and Fersht, 1995; Creighton, 1993; Levitt, 1983; Wolynes, 1990; Larhed and Hallberg, 2001; Dutton, 2002). One interesting aspect that has not been much addressed is to what extent external radiation can cause conformational effects. It has been proposed (Bohr and Bohr, 2000a; Bohr, Bohr and Brunak, 1996) and demonstrated (Bohr and Bohr, 2000b) earlier that microwaves can cause such effects through a stimulation of the coherent intrinsic dynamics in biomolecular chain molecules, for example, DNA, RNA, and proteins. Such behavior is consistent with the view that protein folding can be considered as the result of a competition between torsion and bending forces, and not only driven by entropy (Bohr and Bohr, 2000a; Bohr, Bohr and Brunak, 1996). Folded structures that are

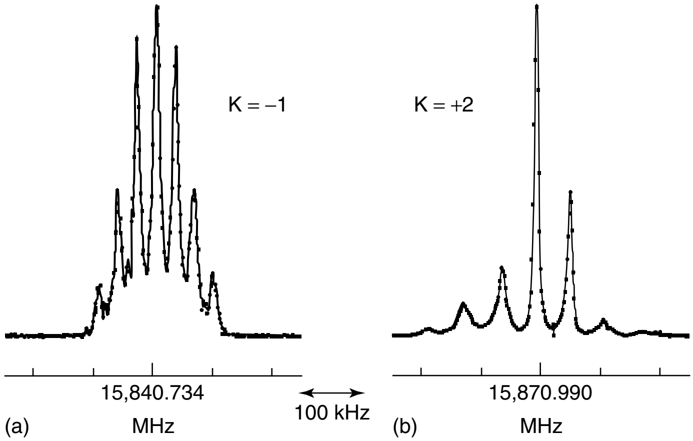

Fig. 15.2 A constructed picture of a spectrum in a large region containing rotational, vibrational, and electronic excitation, all appearing as absorption spectroscopy (Arunan and Gutowsky, 1993).

stabilized by hydrogen bonds, disulfide bridges, and so on, can maintain a significant fraction of folding in balance with unfolded chains, and the biological evolution of living organisms may be considered partly as a selection of proteins with the ability to acquire stable conformations.

An experimental proof for absorption of microwave radiation in protein molecules is given in Chapter 6, see also (Bohr, Jacobsen and Laursen, 2007). For being able to eliminate well-known absorbance of microwave radiation in water, the protein sample was carefully freeze dried and filtered to contain only a few coater molecules per protein molecule and then dissolved in carbon tetrachloride and with a sensitive electron spin resonance (ESR) microwave cavity was shown to exhibit a nonzero absorbance coefficient ε of the relative dielectric constant. The maximum of this absorbance was close to 2.3 GHz in frequency.

Previously, microwave effects have been reported in studies of bond breaking in plasmid DNA (Sagripanti, Swicord and Davis, 1987), in a method for selective peptide-bond cleavage of proteins (Wu *et al.*, 1992; Ramos, Winter and Kielland-Brandt), and in immunostaining of cytopathology specimens (Reynolds *et al.*, 1994). It is expected that these effects certainly include a component that is nonthermal (Bohr and Bohr, 2000b).

15.5
The EM Absorption Spectra of Proteins

Microwave spectra of proteins give unexpected new information about the various modes one can find in axial-symmetric chain molecules.

The much studied part of the electromagnetic spectrum is that of vibrational spectra of biomolecules in the infrared region and, to some extent, the rotational spectra in the higher radio frequency region of 1–10 MHz. The infrared spectra of biomolecules contain the bond vibrations typical for the carbon geometry such as the amide band that is a signal for secondary structures in protein molecules.

The region of 1–10 GHz, being in the lower end of microwave frequencies is not usually expected to entail phenomena concerning biomolecular structures and thus not expected to give rise to any absorption when the biomolecules are being irradiated with microwaves. Absorption is caused only if the solvent contains water as the most common constituent of biological solvents. Water has a strong ability to absorb microwaves due to the rotational energy of the water dielectric giving rise to a large dominant peak around 22 ± 20 GHz, the latter number being due to dispersion. As mentioned above, amino acids have, as can be calculated, rotational spectra in the gigahertz region. Experimentally, the amino acid, glycine, has been found to have a line at around 1 GHz.

In order to distinguish this large factor of absorption by water, which (often) override any phenomena that might be due to other phenomena of microwave irradiation on biomolecules, one must carefully select a solvent that had no absorption of microwave radiation, that is, transparent to microwaves. At the same time, it has to be a solvent that proteins can be dissolved in, without destroying the basic structure of the polypeptide backbone of proteins, although the proteins might undergo a certain degree of unfolding. Thus, one should choose carbon tetrachloride as a solvent for this purpose.

15.5.1
Theory

A possible reason for why microwave can cause structural changes of proteins when being irradiated can be the excitation of collective intrinsic modes in the protein. One can estimate the frequency of intrinsic torsional modes and show that they are well matched to the technical microwave sources with frequencies in the region of 1–3 GHz.

In physical and biological systems, interactions of biological chain molecules will take place with the aqueous environment, with other chain molecules, with membranes, and so on. For closed chain molecules, such as circular DNA, the topological conservation of White (1969) implies that the sum of the torsion and the writhing is constraint to a constant (the linking number). Owing to the finite viscosity of the aqueous medium, proteins are topological restricted when considered on a sufficient short time scale, a fraction of a microsecond and less. The torsion term can be considered separately as there is not sufficient time for the writhing term in the White equation (White, 1969; Fuller, 1971,1978; Crick, 1976). Coherent intrinsic motion of higher frequencies can therefore take place.

The eigenfrequency, ν, can be estimated from a simple calculation of the energy having a rotational and torsion contribution as follows:

$$E = E_{\mathrm{rot}} + E_{\mathrm{tor}} = \frac{1}{2}\left(\frac{\partial\phi(\sigma)}{\partial t}\right)^2 + \frac{1}{2}\alpha\left(\frac{\partial\phi(\sigma)}{\partial\sigma}\right)^2 \tag{4}$$

where σ is a spatial variable along the backbone chain and $\phi(\sigma)$ is a vector field orthogonal to the chain axis measuring the displacement. I is the moment of inertia and α is the torsion constant. The equation of motion is as follows:

$$\left(\left|I\frac{\partial^2}{\partial t^2} - \alpha\frac{\partial^2}{\partial\sigma^2}\right|\right)\phi(t,\sigma) = 0 \tag{5}$$

One might actually, in more analytical terms, write the Lagrangian and derive the full set of the Euler–Lagrange equations:

$$\begin{aligned} L = {} & \frac{1}{2}\frac{M}{L}\int_0^L \left(\frac{\partial \mathbf{r}(\sigma,t)}{\partial t}\right)^2 d\sigma \\ & + \beta\int_0^L \left(\left|\frac{\partial \mathbf{r}(\sigma,t)}{\partial\sigma}\right| - 1\right)^2 \\ & + \frac{1}{2}k_{\kappa,j(\sigma)}\int_0^L (\kappa(\sigma,t) - \kappa_{j(\sigma)})^2 d\sigma \\ & + \frac{1}{2}\alpha\int_0^L \left(\frac{\partial\phi}{\partial\sigma}\right)^2 d\sigma \\ & + \frac{1}{2}\frac{I}{L}\int_0^L \left(\frac{\partial\phi}{\partial t}\right)^2 d\sigma \end{aligned} \tag{6}$$

where k_κ is the bending rigidity constant and α the torsional constant. The bending is represented by the curvature $\kappa = |(\partial^2\mathbf{r}/\partial\sigma^2)|_n$ and the torsion by $\tau = (\partial\phi/\partial\sigma)$. L is the length of the string and M is the total mass. The bending process in the folding of the protein involves several energy minima $j(\sigma)$ parametrized along the string.

The equation of motion (the Lagrange–Euler equation) for the string then becomes:

$$\frac{M}{L}\frac{\partial^2 \mathbf{r}(\sigma)}{\partial t^2}+\frac{I}{L}\frac{\partial^2 \phi(\sigma)}{\partial t^2}=c_1\frac{\partial^2 \mathbf{r}(\sigma)}{\partial \sigma^2}+c_2\frac{\partial^2 \phi(\sigma)}{\partial \sigma^2}+c_3 \qquad (7)$$

We shall study two simple solutions to the corresponding equations of motion by proposing two easy ansatzes. More complicated solutions can be obtained by perturbation around any of the static solutions.

1. Straight rod. The protein as a straight rod is described by all $\kappa_{j(\sigma)}$ being equal to κ_o. In this situation, the elastic restoring force is around the direction of the rod:

$$\mathbf{r}(\sigma)=\mathbf{r}_o+\sigma(\mathbf{r}_L-\mathbf{r}_o)/L \qquad (8)$$

$\mathbf{r}_L$ and $\mathbf{r}_o$ are the start and end positions, respectively. We will now assume that it is physically along the x axis from 0 to L. We obtain the wave solution with the ansatz $\mathbf{r}=\mathbf{r}(\sigma-vt)$ and $\phi=\phi(\sigma-vt)$ that leads to the $\mathbf{r}(\sigma,t)=(L\sigma,0,0)$ solution of longitudinal and transverse oscillations:

Longitudinal oscillations:

$$\mathbf{r}(t\pm v\sigma)=\left(L\sigma+\sum_a a_n \times \cos n(t/v\pm\sigma)/l\pi, 0, 0\right) \qquad (9)$$

Transverse oscillations:

$$\mathbf{r}(t\pm v\sigma)=\left(L\sigma, \sum_b a_n\cos n(t/v\pm\sigma)/l\pi, \sum_c a_n\cos n(t/v\pm\sigma)/l\pi\right) \qquad (10)$$

and torsional oscillations

$$\phi(t\pm v_t\sigma)=\sum b_n\cos n(t/v_t\pm\sigma)/l\pi \qquad (11)$$

We have

a. Pure torsional modes: the rod is fixed while the angular variable can vary in time and space.

b. Pure bending modes: the bending can vary in time and space while the torsion is constantly zero.

2. Helical structure. Here we assume that $\kappa_j(\sigma)$ are equal to κ_o, which means that the restoring force is around a favored curvature. We represent the helical structure by

$$\mathbf{r}=(R\cos(b\sigma), R\sin(b\sigma), a\sigma) \qquad (12)$$

where $R=\sqrt{(1-a^2/b^2)}$ is the radius and a, b are constants. We have

a. Pure torsional modes: the torsion, $\tau=ab$, is changing while the curvature, $\kappa=b\sqrt{b^2-a^2}$, is constant. Stretching the helix leads to a larger radius R.

b. Pure bending modes: the curvature is changing while the torsion is constant. Stretching the helix generally leads to solutions with both smaller and larger radius depending on the exact value of the constants.

The simple version of the equations above is solved with the well-known wave ansatz $\phi(\sigma-vt)$, where the velocity v is given by

$$v=\sqrt{\frac{\alpha}{I}} \qquad (13)$$

The eigenfrequency, ν, can then be derived from the velocity v to be

$$\nu=\frac{1}{L}\sqrt{\frac{\alpha_l}{I}} \qquad (14)$$

where L is the length of the chain molecule that participate in one period of the wring mode, α_l is the torsion constant per inverse unit length and i is the moment of inertia of the backbone per unit length. Typical values are not easy to obtain. For proteins, we may take a rotation of $\pi/2$ to correspond to about 1 eV Å^{-1}, in agreement with common bond energies, although, the energy involved in strained chemical bonds are often smaller. Hence, the torsion constant per inverse unit length, α_l, is about 0.4 eV/. The moment of inertia of the backbone (per unit length), i, is about 100 J s^2, depending on to which degree the side chains are involved in the wringing. A typical value for L is 475 Å, and hence, the frequency ν is in the range of 1–5 GHz. This estimate is based on the assumption of the presence of a linear torsion term. However, as the torsion term is not linear the estimate is only an upper limit. We think that possibly it is a factor of 10 or too large. It should further be noticed that the width of the resonance will be very large because of dispersion. As can be seen, the frequency of such coherent modes in biomolecular chain molecules turn out to be of the same order of magnitude than those typical of radio- and micro-wave applications. Later, we shall give experimental "hints" about the resonance frequency for proteins derived from microwave absorption spectra.

15.5.2
Side Chain Rotors Initiating Wringons

The rotational energy spectrum of the amino acids contains lines that can be related to the wringon-induced twist excitations. Little experimental information is available on rotational spectra of amino acids side chains since they are hard to detect. Often they are referred to as *flip transitions* in the literature. The rotational frequency ω of a side chain group can be calculated from the quantized energy levels (as in Chapter 3):

$$\frac{\hbar^2}{2I}J(J+1), \quad J = 0.1, 2, \ldots \tag{15}$$

where I is the moment of inertia. One can calculate the rotational spectra for various amino acids with a standard program (Emilsson, 1993).

Both tyrosine and phenylalanine have low-level transitions in the interested region and especially the tyrosine line at 1.6 GHz and the phenylalanine line at 2.1 GHz could be the origin of the twist modes. It is appealing to assume that side chain rotors, for example, peptides are important and operating as oscillators for initiating topological resonance phenomena on the polypeptide backbone. This is because nature can exploit the fact that the square of the amplitudes of separate oscillators add up in a constructive interference phenomenon.

15.5.3
Hydrolysis of Proteins and DNA Damages

As mentioned in Chapter 4, bond breaking effects have been detected in a study on microwave radiation applied to plasmid DNA (Sagripanti, Swicord and Davis, 1987). In another study, a method has been developed for rapid and selective peptide-bond cleavage of proteins in a weak acidic solution (Wu *et al.*, 1992).

The energy of a single quanta of microwave is negligible when compared with chemical bonding energies and consequently microwaves is not characterized as ionizing radiation. Therefore, at first it may seem surprising that the electromagnetic energy deposited in DNA can be concentrated and focused in such a way that the energy subsequently can be released for the breaking of a single/double strand. The topological wring modes described above can explain this. Before the breaking of the strand, the energy of the wring mode is distributed along the chain molecule. However, locally the angular strain may lead to conformational changes of the DNA and eventually to breaking. As the DNA breaks, it can no longer support the wring mode that induced the breaking, and the energy is released in the breaking process by a topological process. In Bohr and Bohr (2000a), an illustrative comparison is made between chain molecules (e.g. proteins/DNA) and that of chains of springs, which thereby provide a possible mechanism and explanation for the bond breaking or hydrolysis by microwaves.

15.5.4
Previous Results

In the following is given indirect evidence for microwaves having effect on protein folding. Experiments were carried out on β-lactoglobulin, which was chosen as a test protein because of the accessibility of the cold denaturation, folded, and hot denaturation states. In a 4 M urea solution, the protein has a cold denaturation to folded state transition around 20 °C. The protein is derived from cow milk and has a barrel-like structure. The pronounced content of secondary structure elements is sensitive to polarization measurements as obtained from the Optical Rotational Dispersion (ORD) experiment. Hence, working with β-lactoglobulin provides the advantage of working with the easily accessible cold denaturation phase so that all refolding experiments can exclusively deal with cold denaturation and avoid hot denaturation which often involve protein aggregation. The basic refolding experiment for β-lactoglobulin consists of bringing the sample from the cold denaturation state over to the folded state by raising the temperature from 5 to 44 °C and then back to the cold denaturation state at 5 °C, where the system is allowed to completely equilibrate over about 3 hours. When this refolding experiment is done during a matter of a few hours the heating–cooling cycle will be monitored as a kinetic loop (Figure 15.3). If the measurements at each temperature step are performed with the sample at perfect equilibrium

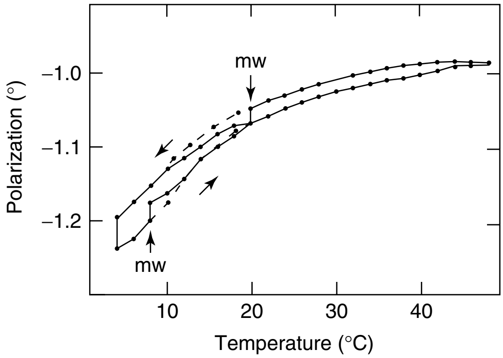

Fig. 15.3 A sketch of the heating–cooling cycle together with applied microwave radiation on a protein (β-lactoglobulin) sample in an aqueous solution. Bohr and Bohr (2000b).

(equilibrium between the concentration of protein in the denatured and folded state) the loop will collapse to a line of polarization values as a function of temperature. The appearance of a kinetic hysteresis loop is a result of the slow-reaction kinetics, and the measurements of the loop therefore allows to study the abrupt changes in the reaction kinetics. The temperature can be monitored inside the sample holder of the polarimeter by a thermocouple wire.

Then, in the next series of experiments the previously described heating-cooling cycles are studied when the microwave irradiation is applied to a protein sample at certain temperatures during the refolding and denaturation process.

The microwave radiation was provided from a standard magnetron of a microwave oven operating at 2.45 GHz and with an effect of 800 W. The microwave oven was remodeled so that it could operate on the sample holder of the polarimeter while it was constantly in contact withthe heath-bath with a circulating silicone liquid. Inside the oven, several containers, containing in all 2 l of water, were placed in order to absorb some of the microwave effect released during the operation. Then microwaves were applied, the sample holder was inserted into the microwave oven without disconnecting it from the heath-bath. The temperature was monitored before and after microwave irradiation. The microwave irradiation was applied for 5 seconds at 800 W causing a temperature increase of the protein sample of about 0.3 °C. The power absorbed by the 3 ml sample was about 0.75 W. Quickly after the microwave irradiation, the sample holder is put back into the polarimeter and the polarization is remeasured.

The previous experiment is repeated starting with the denatured β-lactoglobulin solution equilibrated at 4 °C. First, the temperature is increased to 48 °C without the application of microwaves. Then, the temperature is lowered back to 4 °C while at 20 °C microwaves is applied. After reequilibration at 4 °C, the temperature is raised to 48 °C again. At 8 °C microwaves are applied. The small difference in the polarization values when compared with Figure 15.2a is due to a slight difference in protein concentration in the sample.

Beside the old experiments already published by Bohr and Bohr (1998, 2000b), one has been able to continue with the experiments, trying to change the frequencies of the applied microwave irradiation in the experiment above and hence try to establish the optimal frequency with the largest microwave effects for protein folding/denaturation. Thus, a microwave generator has been applied to a changeable microwave cavity being able to operate approximately in the range of 2–3 GHz but at much lower effect, approximately 10 W, constantly applied in the whole range. The result of the experiment carried out, at the same protein sample and with the same solution as that mentioned above, is shown in Figure 15.3 and shows a clear optimum around 2.4, which corresponds to roughly the same parameters as mentioned or proposed in Bohr and Bohr (2000a).

15.6
Experiments on Absorption of Microwaves in Proteins

The experimental setup is a modified S-band spectrometer for ESR, consisting

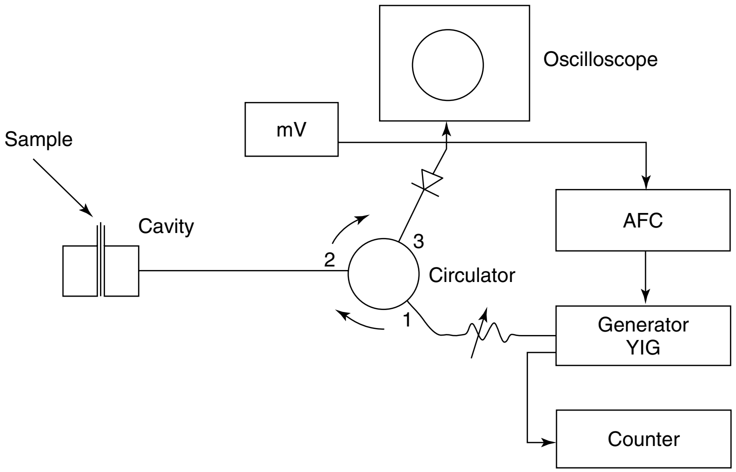

Fig. 15.4 A picture of the experimental setup for measuring microwave absorption of large molecules.

mainly of a YIG-oscillator, a circulator, a high-Q cavity, a counter, and a diode and a digital millivoltmeter (Figure 15.4). Power from the oscillator is lead through the circulators port 1 and 2 to the cavity, which is coupled near critical. The power reflected from the cavity passes the circulators port 2 and 3 to be detected by the diode. The resulting DC/AC voltage V is measured by the DC-millivoltmeter and a scope.

By means of a control circuit connected to the oscillator (AFC), frequency setting and frequency modulation is adjusted. The control unit may be operated in two different modes: a tune mode produces a rather broad frequency modulation and is used for introductory adjustment of the oscillator frequency and cavity coupling as seen on the oscilloscope. A lock mode produces a very small frequency modulation and uses feedback from the diode to lock the oscillator frequency to the resonance frequency of the cavity during measurements.

The rectangular cavity is operated in the TE-101 mode, corresponding to a resonance frequency at around 2350 MHz and a vertical E-field, with maximum at the center of the cavity, where the sample tube is situated. Coupling from the coax line to the cavity is achieved by means of a loop at the end of the line, adjustable to obtain a slightly under critical coupling. In this situation, a larger microwave absorption in the sample will produce a larger reflected power from the cavity and a higher numerical value of diode output. Assuming only small perturbations of the total absorption in the cavity, the measured changes of diode voltage V may be considered linearly dependent on sample absorption, $\Delta V = C\varepsilon''$, where the constant C depends on microwave power, cavity coupling and Q, sample filling factor and diode sensitivity. However, instead of calculating C, we compare $\Delta V(p)$ for protein with $\Delta V(w)$ measured after addition of 10 μl of water.

Therefore, the procedure was to measure first the diode voltage $V(1)$ for a pure CCl_4 sample and next $V(2)$ for CCl_4 + protein. The difference $\Delta V(p) =$

$V(1) - V(2)$ is then taken as a measure of absorption due to protein in the sample. Finally, $\Delta V(w)$ corresponding to the difference between (i) pure CCl_4 and (ii) $CCl_4 + 10\,\mu l$ water was measured for comparison.

15.7
Results and Discussion

In Table 15.1 is presented the measured diode voltages V corresponding to power reflected from the cavity at resonance for the cases (i) no sample material, (ii) pure solution, and (iii) solution and protein. The average value at 2.30 GHz is $V(p) = 1.7$ mVDC. For the difference between (i) pure CCl_4 and (ii) $CCl_4 + 10\,\mu l$ water, we found $\Delta V(w) = 2.5$ mVDC, that is, the same order of magnitude as $\Delta V(p)$ for the protein. According to results from optical measurements of attached water in the protein solution, the water content in the protein sample is far less than 10 µl. Therefore, we conclude that the absorption measured for the protein solution must be almost entirely due to the protein itself and not to water impurities in the solution or to water attached to the protein molecules. The increase of absorption $\delta\varepsilon''$ due to the protein itself may be calculated using the known absorption of water for calibration. From (Mansfield, 1994) we find $\varepsilon''(w) = 12.0$ at 3 GHz and 25 °C. When weighing these data with the values of δV measured and the volumes of protein solution and water, respectively, we found $\delta\varepsilon'' = 0.20$.

The eigenfrequency, ν of the cavity is strongly dependent on the exact geometry of the cavity and can be altered by adding metallic pieces on strategic positions of the cavity and sample box. This metallic box has closable holes in the top in which biochemical samples in plastic tubes can be submerged into the inner vacuum of the cavity.

In Table 15.2 is presented the average values of $\Delta V(p)$ at three

Tab. 15.2 Change of diode voltage and corresponding protein absorbance at three different frequencies, ν.

Frequency ν(GHz)	V(1) mV for pure CCl_4	V(2) mV for pure CCl_4 + protein	ΔV(p) mV	$\Delta\varepsilon''$
2.167	37.1	37.5	0.4	0.06
2.345	69.7	71.4	1.7	0.20
3.050	51.5	53.4	1.9	0.10

different frequencies. Taking ε'' at 2.345 GHz as reference, one may find the corresponding values for the other two frequencies, utilizing that $\varepsilon''(p)$ is proportional to $\Delta V(p)$ and of the cavity volume, which is again proportional to $\propto \nu^{-3}$ (Lax and Button, 1962). Thus, one finds the values of ε'' indicated in Table 15.2, showing that frequencies of around 2.3 GHz exhibit maximum in absorbance.

The main conclusion of this study is that proteins, that have been carefully dehydrated, do absorb electromagnetic radiation in the microwave range with a maximum absorption at the frequencies around 2.4 GHz. Correspondingly, the ORD measurements under the influence of microwave irradiation, which have been reported in earlier studies (Bohr and Bohr, 2000a,b), is briefly shown in Figure 15.3. A novel observation on ORD with varying microwave frequency shows a maximum effect around 2.35 GHz. The absorption data in Tables 15.1 and 15.2 are in agreement with the ORD data, with respect to the optimal frequency of irradiation being somewhat around 2.4 GHz. The ESR absorption experiments were performed at 10 W generated by AC circuits, amplifiers, and using adjustable MW cavities.

17.1
Introduction

Bilayer-spanning ion channels are ubiquitous constituents of prokaryotic and eukaryotic plasma (and organellar) membranes (Hille, 2001); channel-encoding genes are found even in viral genomes (Pinto, Holsinger and Lamb, 1992; Kang *et al.*, 2004). Ion channels serve many biological functions by being conduits for rapid, regulated ion movement across cellular membranes. Notably, they allow for the changes in membrane potential that underlie the function of the nervous system (Fain, 1999) and other excitable tissues.

Ion conducting channels catalyze transmembrane ion movement by forming continuous paths through which ions can cross the barrier imposed by the membranes' lipid bilayer moieties (Hille, 2001; Andersen and Koeppe, 1992; Chung, Andersen and Krishnamurthy, 2007). In biological membranes, integral membrane proteins provide the structural basis for ion channels by forming the walls of water-filled, high-dielectric pores that allow for electrodiffusive ion movement from one aqueous phase to the other. Ion channels thus provide an alternate permeation (or reaction) path for transmembrane ion movement, in the sense that the permeating ions do not cross the membrane by moving through the bilayer hydrophobic core *per se* (Figure 17.1).

17.1.1
Ion Channels Are Not Just Water-Filled Pores

Most channels are not just "simple" water-filled pores; they possess substrate specificity (ion selectivity) and so can discriminate between chemically closely related ion species such as K^+ and Na^+ (Hille, 2001). That is, ion channels are highly specific protein catalysts or enzymes (Andersen, 1989; Eisenberg, 1990). Ion channels constitute a special class of enzymes, however, because no covalent bonds are made or broken during the ions' passage through a channel pore.

Although channel pores are generally water-filled, some pores are so narrow that the water chain is interrupted by the permeating ions, as shown for the selectivity filter in potassium channels (Doyle *et al.*, 1998), in which the water molecules are separated by K^+. It also has been proposed that H^+ movement through voltage-dependent proton channels proceeds

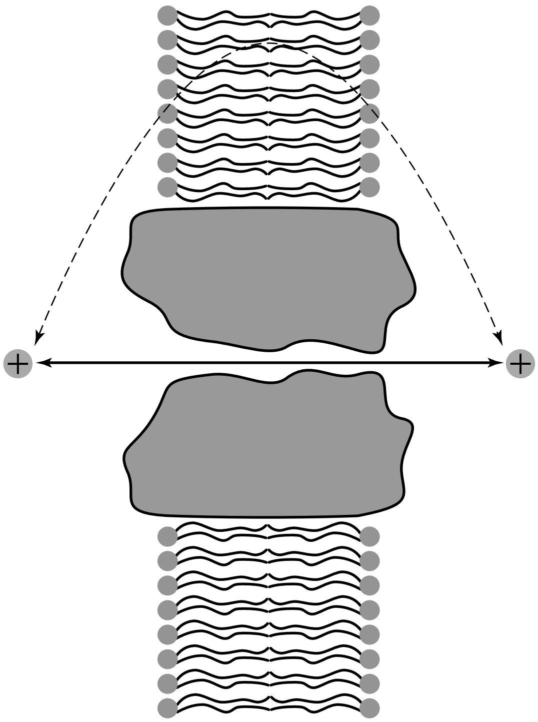

Fig. 17.1 Channel-mediated ion movement. The channel protein forms the walls of an aqueous pore through which ions, water, and other small solutes can move across the membrane (indicated by the solid line). Ions can also traverse the membrane by moving through the bilayer itself (indicated by the interrupted curve). Because the solubility of small inorganic ions in the membrane interior is very low, this uncatalyzed ion movement through the lipid bilayer core usually can be ignored

along a hydrogen-bonded network that may not contain a continuous chain of water molecules (DeCoursey and Cherny, 1998).

17.1.2
Ion Channels Are Efficient Catalysts of Transmembrane Ion Movement

Similar to other enzymes, the important determinants of ion channel function are the channels' substrate specificity (ion selectivity), their turnover number and catalytic power, and their regulation. Because no covalent bonds are formed or broken when ions pass through a channel, the energy barrier for channel-catalyzed ion movement may be quite low. A distinguishing feature of ion channels, therefore, is their turnover number, which can be $> 10^8\ \mathrm{s}^{-1}$ (Latorre and Miller, 1983) – as compared with $< 10^6\ \mathrm{s}^{-1}$ for most regular enzymes (see Hille (2001), Table 11.2A) – and a turnover number greater than $10^5\ \mathrm{s}^{-1}$ is commonly considered to be a defining feature of ion channels. Though there is no lower bound on the ion flux through membrane-spanning channels, the typically very high turnover allows for electrophysiological measurements of ion movement (the single-channel current) through individual channels (Figure 17.2).

Indeed, the first single-molecule measurements were single-channel recordings (Bean *et al.*, 1969; Hladky and Haydon, 1970), which provide the ability to resolve single-channel current transitions (single protein conformational transitions) at the microsecond timescale (Maconochie, Fletcher and Steinbach,

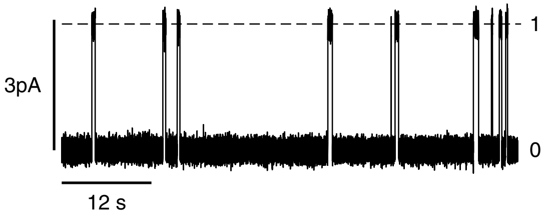

Fig. 17.2 Single-channel current trace recorded in planar lipid bilayers doped with gramicidin A (gA). The gA channels do not open and close but form and disappear. The numbers to the right in the figure indicate the number of conducting channels; the stippled line indicates the current level for the conducting channel. Experimental conditions as described in Greathouse *et al.* (1999) in 121.0 M NaCl, 200 mV applied potential, and dioleoylphosphatidylcholine/*n*-decane bilayer

1995; Shapovalov and Lester, 2004). The high temporal resolution provided by electrophysiological measurements makes ion channels important not only because of their intrinsic physiological functions but also because they can be used as tools to study general features of (membrane) protein function.

Ion movement through ion channels occurs as an electrodiffusive barrier crossing, in which the ion movement is largely uncoupled from protein conformational transitions. To appreciate ion channels' catalytic power, it is instructive to compare the measured conductances with predictions based on a simple water-filled pores with solvent properties similar to bulk water, while neglecting the diffusional access resistance to the channel entrance (Läuger, 1976; Andersen, 1983). In this case, the predicted single-channel conductance for monovalent ions, g_{pred}, becomes (Andersen, Koeppe and Roux, 2007, p. 51):

$$g_{\mathrm{pred}} \approx \lambda^{\circ} C \frac{\pi (r_p - r_i)^2}{l_p} \qquad (1)$$

where λ° is the limiting molar conductivity (a measure of the ion mobility in bulk aqueous solutions, units $(\mathrm{S \cdot cm^2})\ \mathrm{mol^{-1}}$), C the permeant ion concentration in the bulk aqueous phase, r_p the pore radius, r_i the ionic radius, and l_p the pore length. [The appropriate radius in Eq (1) is the difference between r_p and r_i because the ion centers are constrained to move within a narrow cylinder of radius $r_p - r_i$ (Ferry, 1936).] For $\mathrm{Na^+}$ permeation through the cation selective gA channels [$\lambda^{\circ}_{\mathrm{Na}} = 50.1\ (\mathrm{S \cdot cm^2})\ \mathrm{mol^{-1}}$ (Robinson and Stokes, 1959), $r_{\mathrm{Na}} \approx 0.95$ Å (Hille, 1975a), $r_p = 2$ Å, and $l_p = 25$ Å (Finkelstein and Andersen, 1981)], g_{pred} is predicted to be about ≈ 70 pS in 1.0 M NaCl and 7 pS in 0.1 M NaCl – similar to the experimental values of 12.5 pS (in 1.0 M NaCl) and 5.3 pS (in 0.1 M NaCl) (Finkelstein and Andersen, 1981). This similarity does not mean that ion channels are just aqueous pores. Ions may bind with high affinity into the pore of ion channels, such that the ion mole fraction in the pore may be several orders of magnitude higher than in the aqueous solution (see next section).

17.1.3
Catalytic Rate Enhancement

It is possible to extend this argument by estimating the catalytic rate enhancement provided by an ion channel (Andersen, Koeppe and Roux, 2007). By analogy with conventional enzymes (Wolfenden and Snider, 2001), the catalytic rate enhancement can be defined as the rate of channel-mediated ion movement (k_{cat}) relative to the rate of noncatalyzed movement through the bilayer (k_{non}). To a first approximation, $k_{\mathrm{cat}}/k_{\mathrm{non}}$ can be equated with $K_{w\to p}/K_{w\to m}$, where $K_{w\to p}$ and $K_{w\to m}$ denote the ion partition coefficients from bulk water into the pore and the bilayer hydrophobic core, respectively. $K_{w\to p}$ can be estimated from apparent dissociation constants for the permeant ions, which are in the micromolar range for calcium (Almers and McCleskey, 1984) and potassium (Neyton and Miller, 1988) channels. That is, $K_{w\to p}$ can be approximated as $n_i{}^p/n_i{}^b$, where $n_i{}^p$ and $n_i{}^b$ denote the ion mole-fractions in the pore and the bulk solution, which can be as high as 10^6. $K_{w\to m}$ can be estimated from the "leak" conductance ($G_0 \approx 10^{-9}$ S cm^{-2}) of unmodified bilayers in 1.0 M salt (Hanai, Haydon and Taylor, 1965) using the relation (Andersen, 1989; Hodgkin and Katz, 1949)

$$G_0 = N_A \frac{(ze)^2}{k_B T} \frac{D_m}{d_0} K_{w\to m} C \qquad (2)$$

where N_A is Avogadro's number, k_B Boltzmanns constant, T the temperature in Kelvin, z the ion's valence, e the elementary charge, and D_m the ion's diffusion coefficient in the bilayer hydrophobic core [about 10^{-5} cm$^2\cdot$s^{-1} (Schatzberg, 1965)]. On the basis of Eq. (2), $K_{w\to m}$ is predicted to be 10^{-14} (or less), such that the catalytic rate enhancement may be as high as 10^{20} – higher than the rate enhancements observed for conventional enzymes (Wolfenden and Snider, 2001).

17.2
Channels and Diseases

Because ion channels are such effective catalysts for transmembrane ion movement, disruptions in channel function can lead to disease, and an increasing number of human diseases have been shown to be caused by abnormal channel function caused by mutations in channel genes (Ashcroft, 2006; Cannon, 2006). These so-called channelopathies can develop from defective channel synthesis that is caused by missense mutations or splice defects (Cannon, 2006), inappropriate trafficking of the mutant channels to their target membrane [as is the case for the cystic fibrosis transmembrane conductance regulator or CFTR channel (Du, Sharma and Lukacs, 2005)], or channel retrieval [as is the case for the epithelial sodium channel (ENaC) in Liddle's syndrome (Rossier *et al.*, 2002)]. They also can develop from altered gating, which may increase or decrease the number of conducting channels (Bennett *et al.*, 1995); altered ion selectivity, which may disrupt the cellular electrolyte and volume balance (Kofuji *et al.*, 1996); or the appearance of new channel functions such as novel pathways for ion movement (Sokolov, Scheuer and Catterall, 2007), which again may compromise the cellular electrolyte and volume balance (Struyk and Cannon, 2007).

17.3
Diversity of Ion Channels

Ion channels can be classified based on their structure and function. Structurally, ion channels are usually hetero- or homo-oligomers of pore-forming subunits, sometimes in association with accessory/modulatory subunits. Channels in plasma membranes have predominantly α-helical bilayer-spanning transmembrane (or TM) domains, whereas channels in bacterial outer membranes (and the outer membrane of mitochondria) have a predominantly β-barrel structure (Figure 17.3). Although the focus is usually on the TM domains, for many

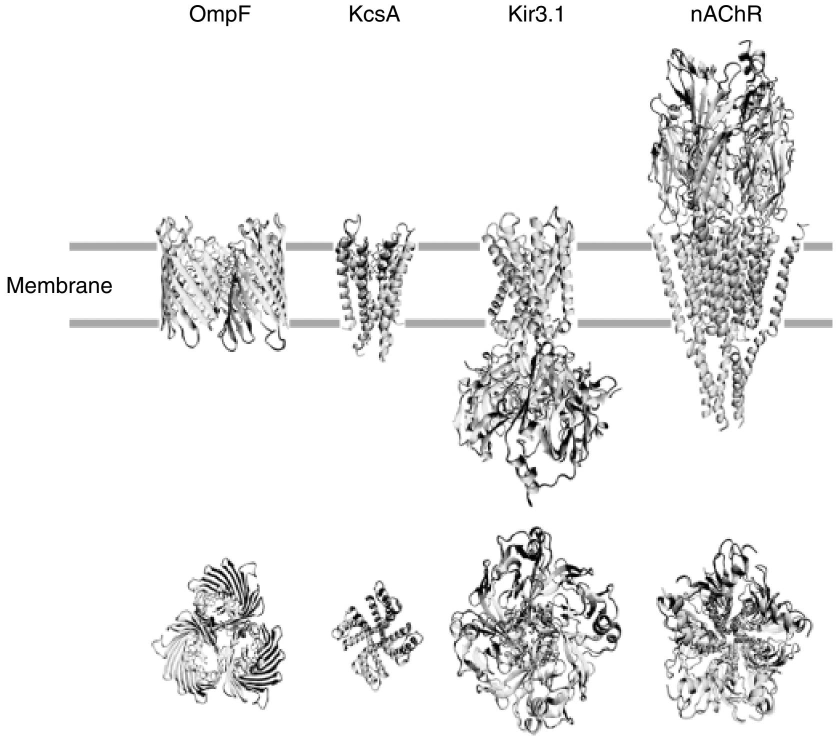

Fig. 17.3 Structural representation of different transmembrane ion channels (from left to right): the bacterial outer membrane protein OmpF [PDBid: 1OPF (Cowan *et al.*, 1995)]; the bacterial potassium channel KcsA [PDBid: 1 K4C (Zhou *et al.*, 2001)]; a chimera between the mammalian inward rectifier potassium channel Kir3.1 and the bacterial inward rectifier KirBAC1.3 [PDBid: 2QKS (Nishida *et al.*, 2007); in this structure a large part of the transmembrane pore domain of Kir3.1 has been replaced by the corresponding fragment of the pore domain of the prokaryotic KirBac1.3]; and the mammalian nicotinic acetylcholine-gated channel nAChR [PDBid: 2BG9 (Unwin, 2005)]. α-Helices are indicated as coiled ribbons, β-sheets as straight ribbons, and the loops as lines. Top row: side views of the channels relative to the outer membrane (OmpF, with the periplasmic surface down) or the plasma membrane (KcsA, Kir3.1, and nAChR, with the intracellular surface down). Bottom row: the channels viewed along the pore: OmpF is viewed from the periplasmic solution; KcsA and nAChR are viewed from the extracellular solution; and Kir3.1 is viewed from the intracellular solution. The biological unit of the OmpF consists of three functional channels, and each pore is formed by a single subunit. The KcsA and Kir3.1 channels are formed by four subunits that line a single pore; the nAChR channel is formed by five subunits that line a single pore

channels, majority of the molecular mass is outside the membrane, illustrated in Figure 17.3 for a Kir3.1 chimera and nicotinic acetylcholine receptor (nAChR).

Functionally, ion channels are distinguished by their permeability and gating properties and by their cellular localization. Most channels are valence selective, and many channels exhibit exquisite selectivity among ions of the same valence [as indicated by their names – calcium channels, chloride channels, potassium channels, and sodium channels, e.g., Hille (2001)]. The major exceptions are the large-diameter channels, such as the porins in the outer membranes of gram-negative bacteria and the connexins (or gap junctions) that couple adjacent cells together – both electrically and by mediating cell-to-cell movement of low-molecular weight signaling molecules (Harris, 2001). These channels allow for the relatively nonselective transmembrane movement of both anion and cations (Harris, 2007), yet such channels may exhibit selectivity among (larger) organic solutes (Harris, 2007; Kullman, Winterhalter and Bezrukov, 2002; Kanaporis *et al.*, 2008). Indeed, although channels with large-diameter pores allow for the passage of large solutes, they do not necessarily have high single-channel conductances; no clear relation is found between a channel's pore dimensions and its conductance (Finkelstein, 1975).

Ion channel function may be altered by changes in the surface density of channels in the membrane as well as by rapid transitions between nonconducting and conducting channel states – a process denoted as *channel gating*. The two classic examples of channel gating are the *voltage-dependent gating* (described in Section 17.5.4) of sodium and potassium channels that underlie the action potentials in nerve and muscle cells, in which the channel state is controlled by the transmembrane potential, and the *ligand-dependent gating* (described in Section 17.5.3) of the channels involved in synaptic (chemical) transmission of electrical signals from cell to cell, such as the nAChRs in skeletal muscle, in which the channel state is controlled by ligand (acetylcholine) binding (Hille, 2001). The principles underlying channel gating are discussed in Section 17.5.

17.3.1
Classification of Ion Channels

Tables 17.1 and 17.2 list ion channels according to their gene superfamilies, number of TM (α-helical) segments, and function. The emphasis is on plasma membrane channels because most is known about them.

17.3.1.1 Pore-Loop Channels

The largest family of plasma membrane ion channels is the family of pore-loop channels, listed in Table 17.1. The defining feature of these channels is their central core, which forms the ion permeable pore with the pore lining being formed by two TM α-helices plus the intervening sequence that loops into the membrane to form the selectivity filter – the pore region that determines which ions can permeate the channel. The archetypical example of this so-called 2TM,1P (P for pore) motif is found in the KcsA channel (Figure 17.3), the first ion-selective plasma membrane channel whose high-resolution structure was determined (Doyle *et al.*, 1998). The channel is a tetramer of four pore-forming 2TM,1P subunits, in which the

Tab. 17.1 Ion channel classes: plasma membrane pore-loop and cys-loop channels.

Channel class	Organization	Type	Properties	Reference
Pore-loop channels	2TM,1P (tetramers)	KcsA	K^+ selective (proton gated)	Doyle *et al.* (1998) and Chakrapani, Cordero-Morales and Perozo (2007a, 2007b)
		Kir	K^+ selective (inward rectifying)	Lu (2004) and Kubo *et al.* (2005)
	4TM,2P (dimers)	K_{2P}	K^+ selective (nonrectifying; stretch- and amphiphile gated)	Goldstein *et al.* (2005) and Honore (2007)
		K_V	K^+ selective (voltage dependent)	Gutman *et al.* (2005) and Korn *et al.* (2007)

selectivity filter is lined by four extended peptide strands (one from each subunit) in a loop between the TM helices. This bilayer-spanning motif is found not only in KcsA but also in the Kir family of inward rectifier potassium channels (Kubo *et al.*, 2005); the latter class of channels also has a large cytoplasmic domain (cf. Figure 17.3).

The basic 2TM,1P motif has evolved in three different directions (Figure 17.4). The first direction evolved by a process of internal gene duplication that led to the so-called 2-pore (K_{2P}) channels with a 4TM,2P organization. The second direction evolved by a more complex process that involved an inversion of the TM topology, the accretion of an additional TM segment, plus an extracellular domain with sequence similarity to bacterial periplasmic amino acid binding proteins (Wo and Oswald, 1995), which led to the glutamate receptor family of ligand-activated channels with a 3TM,1P organization. And the third direction evolved by acquiring a 4TM voltage-sensing domain [that by itself can form a voltage-dependent proton channel (H_V) (Musset *et al.*, 2008)] leading to the 6TM,1P group of channels, which are largely potassium selective and include the voltage-dependent potassium channels (K_V). This 6TM,1P motif has evolved into the 7TM,1P family of high-conductance Ca^{2+}-activated potassium channels (K_{Ca} or BK, for Big K^+ channel), which also have large C-terminal Ca^{2+} binding domains. Finally, the 6TM,1P motif also evolved by internal gene duplication to form the so-called two-pore channels that have two domains and the voltage-dependent sodium (Na_V) and calcium (Ca_V) channels that have four domains. In both cases, each domain corresponds to a duplicated 6TM,1P pore-loop motif. [The emphasis in Tables 17.1 and 17.2 and Figure 17.4 is on the pore-forming subunits, called *α subunits*; functional channels are usually coassemblies of four pore-forming subunits or

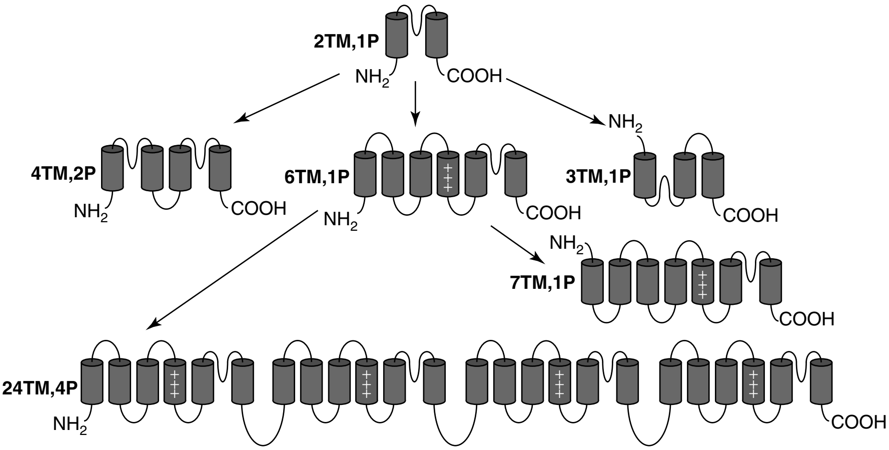

Fig. 17.4 Schematic diagram that shows the TM segment organization for different pore-loop plasma membrane ion channels (listed in Table 17.1). The ancestral 2TM,1P motif (exemplified by KcsA; Figure 17.3) has evolved by gene duplication and the accretion of additional TM domains – and an inversion of transmembrane topology in the case of the 3TM,1P glutamate receptors

domains plus additional cytoplasmic or TM regulatory subunits (Hille, 2001).]

17.3.1.2 Cys-Loop Channels

Another major family of plasma membrane ion channels is the family of ligand-gated Cys-loop receptors, also listed in Table 17.1. These channels can be subdivided based on their activating ligand: acetylcholine (ACh) for the nAChR (Figure 17.3); serotonin (5-HT) for the 5-HT_3R; glycine (Gly) for the GlyR; and γ-aminobutyric acid (GABA) for the $GABA_AR$. ACh, 5-HT, and GABA also bind to other receptors, for example, muscarinic acetylcholine receptor (AChR) and $GABA_BR$, which are G-protein-coupled receptors. These channels also can be categorized based on their ion selectivity and function: nAChR and 5-HT_3R are cation selective channels involved in excitatory synaptic transmission and $GABA_AR$ and GlyR are anion-selective channels involved in inhibitory synaptic transmission. [In addition to the listed channels, a H^+-gated Cys-loop channel has been reported (Beg *et al.*, 2008).]

17.3.1.3 Other Channel Types

The remaining channel types, listed in Table 17.2, are more difficult to categorize, and many of them have no obvious evolutionary relationship.

The major exception is the family of ENaCs, the mechanosensitive channels (Deg, for degeneration because Deg activation triggers cell death) first identified in *Caenorhabditis elegans*, and the H^+-gated sodium channels (ASIC, acid sensitive ion channel) found in various cell types. These channels are also related to a family of invertebrate peptide-gated channels [the FMRFamide-gated channels (Lingueglia, Deval and Lazdunski, 2006)].

There may also be an evolutionary relationship between the intracellular Ca^{2+} release channels, the ryanodine receptors (RyRs) that mediate the release of Ca^{2+} from the sarcoplasmic reticulum, and the IP_3 receptors (IP_3Rs) that mediate the release of Ca^{2+} from many intracellular organelles.

In the family of ClC proteins, some members are expressed in the plasma membrane where they form anion-selective channels. These channels occur as dimers, with each subunit forming a TM pore. Other members of this family are expressed in organellar membranes, where many of them form H^+/Cl^- countertransporters (Jentsch, 2008), as first demonstrated for a bacterial plasma membrane ClC protein (Accardi and Miller, 2004) – thereby validating a conjecture by Läuger (1980) that there would be a continuum of molecular mechanisms catalyzing TM solute movement, ranging from conformational transporters to TM channels.

The porins in the outer bacterial and mitochondrial membranes serve as conduits to the periplasmic space. Some porins occur as oligomers, each forming a TM pore (Figure 17.3). Many porins and the voltage-dependent anion-selective channel (VDAC) appear to catalyze the relatively nonspecific transfer of solutes below a certain size; other porins are involved in more specific solute transfer (Duy, Soll and Philippar, 2007). The H^+ permeable M2 channel, which is encoded by the influenza virus, is important for viral replication and is the target for the antiviral drug amantadine (Pinto and Lamb, 2006).

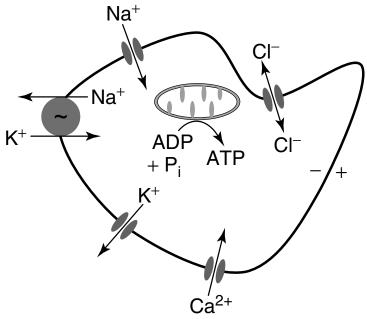

Fig. 17.5 Schematic representation of a cell, with channels that are selective for Cl$^-$, Ca^{2+}, K$^+$, and Na$^+$ plus the Na$^+$-, K$^+$-ATPase that maintains the ion distribution between the extracellular and intracellular compartments via an ATP-driven extrusion of Na$^+$ and uptake of K$^+$. The ATP is generated in the mitochondria by oxidative phosphorylation from ADP and inorganic phosphate (P$_i$). In resting cells, when no net charge movement is across the plasma membrane, the intracellular compartment is electrically negative relative to the extracellular compartment

17.4
Ion Permeation and Membrane Potentials

Most cell membranes are endowed with different types of ion channels (Figure 17.5) that differ in their ion selectivity and gating properties (cf. Tables 17.1 and 17.2).

Because the extracellular and intracellular ion concentrations differ (Table 17.3), the membrane potential ($V_m = V_i - V_e$, where V_i and V_e denote the electrical potential of the intracellular and extracellular compartment, respectively) will vary as a function of the number and type of conducting channels in the membrane (Section 17.4.3).

Although channel-catalyzed ion movement occurs as an electrodiffusive barrier crossing (Andersen, 1989; Cooper, Jakobsson and Wolynes, 1985; Levitt, 1986; Gates, Cooper and Eisenberg, 1990; Partenskii and Jordan, 1992; Kuyucak, Andersen and Chung, 2001; Roux *et al.*, 2004), the permeating ions are usually not distributed uniformly along the pore; they tend to be localized in discrete regions, or energy minima (e.g. see Doyle *et al.* (1998)), such that the ion movement can be approximated as a series of discrete transitions: entry, translocation through the pore, and exit (Figure 17.6).

Although the kinetics of channel-mediated ion movement may be described using discrete-state kinetics, the individual transitions depicted in Figure 17.6 extend over distances that are much longer than the ions' mean free path, which means that one cannot use Eyring's transition state theory with a prefactor of k_BT/h, where his Planck's constant, to relate the measured/deduced rate constants to an underlying energy profile (Andersen, 1999).

17.4.1
Membrane Potentials and Single-Channel Currents

The rate of ion movement through a channel, the single-channel current (i), varies as a function of V_m and the channel's reversal potential, V_{rev}, defined as the membrane potential where $i = 0$:

$$i = g(V_m - V_{\text{rev}}) \tag{3a}$$

where g is the single-channel conductance, which varies as a function of channel type, the permeant ion concentration(s), and V_m – with

Tab. 17.3 Extracellular and intracellular ion concentrations and equilibrium potentials.

Ion	Extracellular concentration (mM)	Intracellular concentration (mM)	Equilibrium potential (mV)
Na^+	145	~12	+67
K^+	4.5	~150	−94
Ca^{2+}	~1.5	~0.0001	+129
H^+	0.00004	~0.0001	−24
Cl^-	115	~10	−65
$HCO_3{}^-$	25	~10	−24

Ion concentrations in millimoles per liter of water. Values for mammals are modified from Ruch, Patton and Scher (1974), Tables 26-5 and 26-6. The $[Ca^{2+}]$ are the free ion concentrations; intracellular $[Cl^-]$ varies considerably among cell types, ranging from ~ 4 mM in skeletal muscle to ~ 80 mM in red blood cells. The equilibrium potentials were calculated for $T = 37\,^\circ C$ using the listed concentrations.

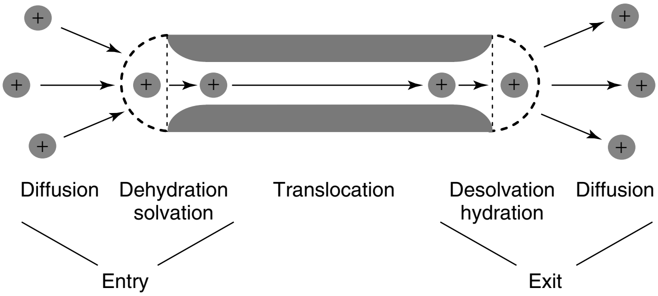

Fig. 17.6 Schematic representation of ion movement through a bilayer-spanning channel. Ions diffuse into the channel entrance, where they undergo dehydration and solvation by polar groups that line the pore wall, translocate through the pore in a diffusive barrier crossing for them to desolvate and rehydrate, and finally diffuse into the bulk solution

most channels having conductances that range between 5 and 50 pS (see Hille (2001), Figure 12.8). The total membrane current (I) that is carried across by all channels of a given type will be

$$\begin{aligned} I &= Ni = Ng(V_m - V_{\text{rev}}) \\ &= G(V_m - V_{\text{rev}}) \end{aligned} \tag{3b}$$

where N denotes the number of *conducting* channels in the membrane and G denotes the total membrane conductance contributed by the channels in question. In the case of highly selective channels that catalyze the TM movement of only a single ion type, V_{rev} becomes equal to the ion's equilibrium (or Nernst) potential E:

$$E = \left(\frac{-k_B T}{ze}\right) \ln\left\{\frac{C_i}{C_e}\right\} \tag{4}$$

where C_i and C_e denote the intracellular and extracellular ion concentrations, respectively. Table 17.3 lists values of E for the four major ions involved in cellular electrical activity. (Strictly, E

should be expressed in terms of the ion activities, but activity coefficients are neglected in Eq. (4) because the ionic strengths of the extracellular and intracellular solutions are similar.)

If only a single type of highly selective ion channels is found in the membrane, then the resting membrane potential – the time-invariant potential of a cell "at rest" when the net current across the membrane is 0 – will be equal to the equilibrium potential for the ion in question. If the membrane is endowed with different types of highly selective ion channels, then V_m becomes a weighted average of the equilibrium potentials for the different ions, for example:

$$V_m = \left(\frac{G_{\text{Na}} E_{\text{Na}} + G_{\text{K}} E_{\text{K}} + G_{\text{Ca}} E_{\text{Ca}} + G_{\text{Cl}} E_{\text{Cl}}}{G_{\text{Na}} + G_{\text{K}} + G_{\text{Ca}} + G_{\text{Cl}}} \right) \quad (5)$$

where the subscripts denote different ions. In the resting cell, G_{K} usually is much larger than the membrane conductances for other ions, so V_m will be close to E_{K}. In general, V_m and the cell functions that are regulated by V_m will vary as a function of the relative contributions of the different ions to the membrane conductance, $G_m = G_{\text{Na}} + G_{\text{K}} + G_{\text{Ca}} + G_{\text{Cl}} + \ldots$

17.4.2
Ion Selectivity

Some ion channels, notably potassium and calcium channels, have remarkable ion selectivity, to the extent that one in many cases can neglect the movement of other ions. Most ion channels, however, are measurably permeable to several different ions, in which case their V_{rev} will vary as function of the permeant ion concentrations and the ions' relative permeabilities, as expressed by the so-called Goldman–Hodgkin–Katz equation (Eq. (1)), which for monovalent cations becomes

$$V_{\text{rev}} = \frac{-k_B T}{e} \ln \left\{ \frac{P_{\text{Na}}[\text{Na}^+]_i + P_{\text{K}}[\text{K}^+]_i}{P_{\text{Na}}[\text{Na}^+]_e + P_{\text{K}}[\text{K}^+]_e} \right\} \quad (6)$$

where P_{Na} and P_{K} denote the permeability coefficients for Na^+ and K^+, respectively, and the ratio $P_{\text{Na}}/P_{\text{K}}$ is a measure of the channel's ability to discriminate between Na^+ and K^+. [Eq. (6) is widely used to quantify ion channels' selectivity, but it is an approximation that is valid only in special cases (Hille, 1975b; Hille and Schwarz, 1978); the permeability ratios, e.g. $P_{\text{Na}}/P_{\text{K}}$, therefore should be regarded as empirical descriptors of a channel's ion selectivity.]

Table 17.4 lists representative values for the permeability coefficients of different channels types (both selective and nonselective cation permeable channels as well as anion permeable channels) and V_{rev} calculated using the ion concentrations in Table 17.3 and Eq. (6). (See Hille (2001), Chapter 14, for a more extensive compilation and discussion.)

Comparing the ion equilibrium potentials in Table 17.3 with the channel reversal potentials in Table 17.4 shows that a channel's reversal potential may differ substantially from the name-giving ion's equilibrium potential.

17.4.3
Membrane Potential Changes and Transmembrane Charge Movements

Ion channels provide the structural underpinnings for the ion movements that underlie the rapid changes in membrane potential that are involved in the electrical signaling (the action

Tab. 17.4 Ion selectivities and reversal potentials for selected ion channels.[a]

Channel type	Permeability ratio	V_{rev} (mV)
Voltage-dependent sodium channel (Na_v)	$P_K/P_{Na} < 0.1$	$> +45$
Epithelial sodium channel (ENaC)	$P_K/P_{Na} \approx 0.001$	$+66$
Voltage-dependent potassium channels (K_v)	$P_{Na}/P_K < 0.01$	< -86
Voltage-dependent calcium channels (Ca_v)	$P_{Na}/P_{Ca} \approx 0.0008$ $P_K/P_{Ca} \approx 0.0003$	$+63$
Cyclic nucleotide-activated channels (CNG)	$P_K/P_{Na} \approx 1.1$ $P_{Ca}/P_{Na} \approx 90$	$+17$
Nicotinic acetylcholine receptor (nAChR)	$P_K/P_{Na} \approx 1.1$ $P_{Ca}/P_{Na} \approx 0.2$	-4
$GABA_AR$	$P_{HCO_3}/P_{Cl} \approx 0.4$	-58

[a] Modified from Hille (2001) (Tables 14.2– 14.6), except for $GABA_AR$, where P_{HCO3}/P_{Cl} is, from Fatima-Shad and Barry (1993).

V_{rev} was calculated using the ion concentrations in Table 17.3 and the permeability ratios in Table 17.4 and Eq. (6) ($T = 37\,°C$) or, for channels permeable to both mono- and divalent cations, a generalized version of Eq. (6) (Lewis, 1979).

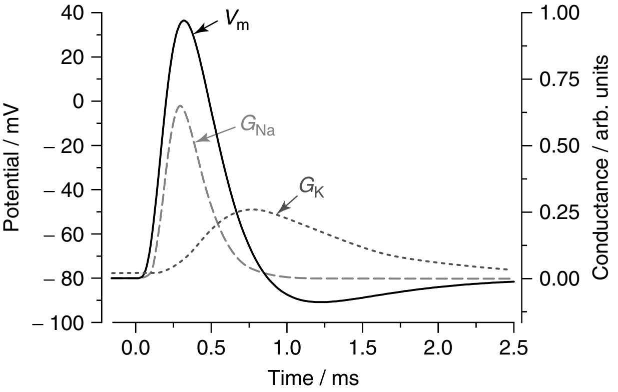

Fig. 17.7 Schematic time course of an action potential. The initial rising, or depolarizing, phase of the action potential is because of an increase in the conductance to Na^+ (G_{Na}). At the peak, the membrane potential approaches the Na^+ equilibrium potential. The later falling, or repolarizing, phase is due to an increase in the conductance to K^+(G_K) and a decrease in G_{Na}. Toward the end of the action potential, the membrane potential approaches E_K because G_K is much higher than at rest

potentials) in nerve and muscle cells (Fain, 1999) and in many other cell functions. Figure 17.7 shows the time course of the potential change during an action potential together with the time courses of the underlying changes in the membrane conductances to Na^+ and K^+. The initial depolarization is due to the rapid activation (opening) of Na_V channels; the later repolarization is because of the slower activation of K_V channels and deactivation and inactivation of Na_V channels, which eventually lead to a transient hyperpolarization (because G_K becomes so large that V_m approaches E_K).

Because cell membranes have a finite capacitance $C_m[C_m = AC_{sp}$, where C_{sp} is the specific membrane capacitance, $\sim 0.9\,\mu F\ cm^{-2}$ (Niles, Levis and Cohen, 1988; Gentet, Stuart and Clements, 2000) and A the membrane area], these changes in membrane potential require only a small TM charge movement ΔQ:

$$\Delta Q = C_m V_m \tag{7}$$

The net ion movements that underlie electrical signaling are minute: according to Eq. (7), a 100 mV change in V_m is associated with a net TM ion movement of $\sim 6 \times\ 10^3$ ions/μm^2. For a spherical cell of radius $10\,\mu$ m, the resulting change in the (volume-averaged) intracellular ion concentration would be $\sim 3\,\mu M$; for a nerve fiber of radius $0.5\,\mu$ m, the intracellular concentration change would be $\sim 40\,\mu M$. The actual ion movements are about threefold higher than the minimum value estimated using Eq. (7) (Hodgkin (1964), pp. 45–46); even then, the changes in V_m that underlie the action potential usually will not cause chemically measurable changes in the intracellular or extracellular ion concentrations (as can be seen by comparing these concentration changes with the concentrations listed in Table 17.3). The major exceptions to this rule are ions that are present at very low concentrations, such as cytoplasmic Ca^{2+} and H^+ [where the concentration changes, however, will be attenuated by cytoplasmic Ca^{2+} and H^+ buffers (Roos and Boron, 1981; Neher, 1995)]; cell processes with a very high surface-area-to-volume ratio (Helmchen, Borst and Sakmann, 1997); and tissues with small extracellular spaces, where K^+ and H^+ can accumulate (Beg *et al.*, 2008; Frankenhaeuser and Hodgkin, 1956; Filosa *et al.*, 2006).

Electrical signaling results from controlled changes in the cell membrane's permeability (conductance) to different ions, which result in changes in V_m (cf. Eq. (5)). The steady-state V_m is determined only by the relative conductances for the different ions (Eq. (5)), but the time course of changes in V_m (such as during an action potential; Figure 17.7) depends on the absolute membrane conductances (channel densities in the membrane). Approximating the change in V_m as an exponential transient with a time constant ($\tau = C_m/G_m$) of $10\,\mu$ s, the membrane conductance will need to be $\sim 10^{-9}$ S μm^{-2} – corresponding to a channel density of $\sim 100\,\mu m^{-2}$ (for channels with $g = 10$ pS) – meaning that a 100 mV change in V_m is associated with a net movement of only ~ 200 ions/channel. Although ion channels have very high turnover numbers, the actual number of ions that move through a channel during an action potential is quite small.

17.4.4
Bulk Ion Movement

In addition to the importance of ion channels for cellular electrical activity, where one to a first approximation can disregard the bulk movement of ions, ion channels serve two additional functions. First, as noted above, in the case of Ca^{2+}, the channel-mediated Ca^{2+} movement may cause a measurable increase in the cytoplasmic $[Ca^{2+}]$, which in turn regulates many different cell functions, including neurotransmitter release, enzyme and hormone secretion, muscle contraction, and gene activation (Berridge, Bootman and Roderick, 2003). Secondly, the bulk absorption of solutes across epithelial membranes depends not only on the presence of adenosine triphosphate (ATP)-dependent ion pumps, in particular the Na^+, K^+-ATPase, but also on the ion channels embedded in the apical and basolateral membranes (Palmer *et al.*, 2007).

17.5
Channel Gating

Ion channel function is tightly regulated to maintain normal function, such as the generation of action potentials, and to avoid compromising the cellular electrolyte, volume, and overall metabolic balance. Channel function is regulated by different stimuli, for example, membrane potential changes, usually positive-going (also called *depolarizing*) potential changes; changes in the concentration of extracellular (neuro)transmitters or intracellular messengers, which may be inorganic ions such as H^+, Ca^{2+}, and Zn^{2+}; light adsorption; covalent modification, such as phosphorylation or dephosphorylation; a mechanical perturbation; and so forth.

17.5.1
Gating Transitions

Channel gating usually involves transitions among different channel states (Figure 17.8): closed, open, and inactivated (in the case of voltage-dependent channels) or desensitized (in the case of ligand-activated channels).

Channel inactivation and desensitization describe transitions from conducting to nonconducting channel states at a sustained membrane depolarization or elevated ligand concentration (Hille, 2001). The inactivated or desensitized states are unresponsive to further depolarization or increases in the activating ligand concentration. The physiological effect of inactivation and desensitization is to reduce ion movement during excessive stimulation.

Whatever the gating mechanism or channel type, the total number of active, that is, conducting or open, channels (N) in a membrane will be equal to the total number of channels of that type in the membrane (N_{tot}) times the probability the channel is in the open state (W_O):

$$N = N_{\text{tot}} W_O \tag{8}$$

where W_O will vary as a function of the stimulus strength and time (after a given stimulus is applied). (Because the letter P is used to denote permeability, we use the letter W, for the German "Warscheinlichkeit," to denote probabilities.)

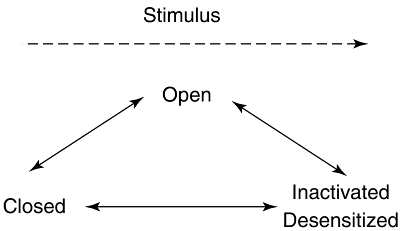

Fig. 17.8 The major transitions in channel gating. An activating stimulus leads to channel opening; the stimulus also causes the channel to enter one or more nonconducting states, which differ from the resting closed states and are denoted inactivated states (in the case of voltage-dependent channels) or desensitized states (in the case of ligand-activated channels)

Channel gating involves transitions among several closed (resting nonconducting) states, one or more open (conducting) states, and, maybe, one or more nonconducting inactivated or desensitized states (Figure 17.8). The principles underlying channel gating can be understood by considering just transitions between two states, closed (C) and open (O), where the stimulus shifts the distribution between the C and O states (Figure 17.9).

17.5.2
Channel Block

In the simplest case (Figure 17.9a), channel gating involves a (voltage-dependent)

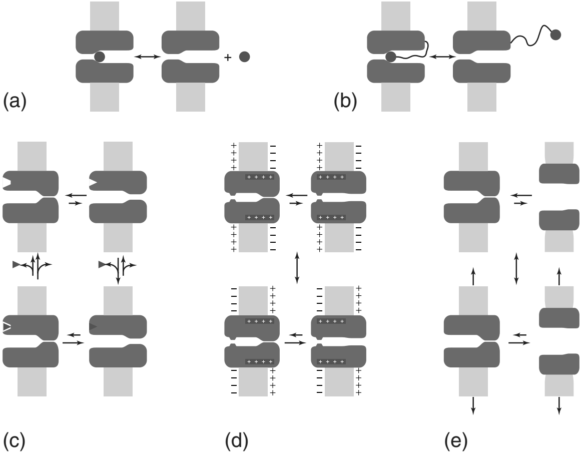

Fig. 17.9 Ion channel gating mechanisms. In each diagram, the extracellular solution is to the left and the intracellular solution is to the right of the channel and its host bilayer. The horizontal arrows in panels a and b denote the reversible transition between the two states; the vertical arrows in the middle of panels d and e denote transitions between the upper and lower equilibria. (a) Block by a small molecule that can enter the pore, where it binds to occlude the lumen and thereby block ion movement. (b) Block by a covalently attached channel domain that is able to enter the pore to occlude the lumen and block ion movement. (c) Ligand activation by a (neuro)transmitter, where the channel exists in two states, nonconducting and conducting, and the equilibrium distribution between the two states is shifted when the activating ligand binds. (d) Voltage activation, changes in the membrane potential (cf. the upper and lower panels) shifts the distribution between different positions of a voltage sensor (indicated by the bar with positive charges); the channel is in the conducting state when the voltage sensor is in the outward position. (e) Mechanical activation, where an increase in membrane tension (indicated by heavy arrows in the middle of each membrane) shifts the distribution between a closed state and an open state that has a greater cross-sectional area

block of the ion permeable pore (Woodhull, 1973). The blocking molecule (B) binds at a site in the pore lumen, and, because electrical potential varies along the pore, B's dissociation constant (K_B) will vary as a function of V_m. In the case of an impermeable cytoplasmic blocker that cannot pass through the pore, the blocker's reaction with the channel can be described as

$$\mathrm{O} + \mathrm{B} \rightleftharpoons \mathrm{OB};\ k_B = \frac{[O]\cdot[B]}{[\mathrm{OB}]};$$
$$k_B(V_m) = k_B(0)\exp\left\{-\frac{ze(1-\delta)V_m}{k_BT}\right\} \tag{9}$$

where O and OB denote the conducting (open) and nonconducting (obstructed) state, z the blocker's valence, and δ the fraction of V_m that falls between the extracellular solution and the site where the blocker binds. The probability that the channel is conducting thus becomes

$$W_O = \frac{k_B(0)\exp\left\{-\dfrac{ze(1-\delta)V_m}{k_BT}\right\}}{k_B(0)\exp\left\{-\dfrac{ze(1-\delta)V_m}{k_BT}\right\}} + [\mathrm{B}] \tag{10}$$

This mechanism describes many aspects of the rectification in inward rectifying potassium channels (Kir; cf. Table 17.1 and Figure 17.3), where cytoplasmic amines such as spermine and spermidine can enter the pore to block ion movement (Lu, 2004). It is also involved in the local anesthetic-induced block of Na_V by (positively) charged anesthetics, although local anesthetics also alter other channel properties (Yanagidate and Strichartz, 2007).

In a more elaborate version of this gating mechanism (Figure 17.9b), the blocking particle is covalently attached to the channel, but still can enter the pore to block ion movement. This mechanism is observed in the fast inactivation of voltage-dependent channels (Yellen, 2002).

17.5.3
Ligand Activation

In the case of ligand-activated channels (Figure 17.9c), such as the Cys-loop receptors (cf. Table 17.1 and Section 17.3.3), an agonist (A) binds with different affinities to the C and O states, and the difference in ligand binding energy to the two states shifts the O/C distribution (Karlin, 1967; Colquhoun, 1973; Jackson, 1989):

$$\frac{L^{CA\to OA}}{L^{C\to O}} = \frac{K_A^C}{K_A^O} = \exp\left\{-\frac{\Delta G_A^O - \Delta G_A^C}{k_BT}\right\} \tag{11}$$

where $L^{C\to O}$ and $L^{CA\to OA}$ denote the equilibrium constant for the interconversion between C and O and between their agonist-bound states CA and OA, respectively; K_A^C and K_A^O denote the dissociation constants and ΔG_A^C and ΔG_A^O denote the standard free energies, respectively, for agonist binding to C and O. The dose-response curve for channel activation by the agonist thus becomes

$$W_O([\mathrm{A}]) = \left(\frac{W_O(0)EC_{50} + W_O(\infty)[\mathrm{A}]}{EC_{50} + [\mathrm{A}]}\right) \tag{12}$$

where $W_O(0)$ and $W_O(\infty)$ denote the channel open probabilities in the limits $[\mathrm{A}] \to 0$ and $[\mathrm{A}] \to \infty$, respectively:

$$W_O(0) = \left(\frac{L^{C\to O}}{L^{C\to O}+1}\right);$$
$$W_O(\infty) = \left(\frac{L^{CA\to OA}}{L^{CA\to OA}+1}\right) \tag{13}$$

and

$$EC_{50} = \frac{L^{C\to O}+1}{L^{CA\to OA}+1}K_A^C = \frac{L^{C\to O}+1}{L^{C\to O}K_A^C + K_A^O}K_A^C K_A^O \qquad (14)$$

is the agonist concentration at which

$$W_O(EC_{50}) = \frac{W_O(0) + W_O(\infty)}{2} \qquad (15)$$

which differs from both K_A^C and K_A^O [cf. Colquhoun (1998)].

The gating of ligand-activated channels is usually more complicated than summarized here, see, for example, Mayer (2006) and Hansen, Yuan and Traynelis (2007). First, channel activation usually involves binding of two (or more) agonist molecules; second, sustained increases in the agonist concentration promote an additional gating transition – to a nonconducting, desensitized state (cf. Figure 17.8) – which is associated with additional conformational transitions (Mayer, 2006; Hansen, Yuan and Traynelis, 2007; Unwin, 1995).

17.5.4
Voltage-Dependent Gating

In the case of voltage-activated channels (Figure 17.9d), such as the 6TM,1P K_V channels or the 24TM,4P Na_V or Ca_V channels (cf. Table 17.1, Section 17.3.2, and Figure 17.4), changes in V_m are sensed by the translocation of charges or reorientation of dipoles by the electric field (Armstrong and Bezanilla, 1973; Bezanilla, 2008). In the case of the voltage-dependent K_V, Na_V, and Ca_V channels, the charge translocation develops from a reorientation of the positively charged S4 segment (Figure 17.4), which leads to an effective TM transfer of about three charges per subunit or domain (Schoppa *et al.*, 1992; Hirschberg *et al.*, 1995). This charge movement is coupled to conformational changes that cause the channel to open when the membrane is depolarized (cf. Hodgkin and Huxley (1952) and Zagotta, Hoshi and Aldrich (1994)). Atomic resolution structures are available for several K_V channels (Jiang *et al.*, 2003; Long, Campbell and Mackinnon, 2005; Long *et al.*, 2007), but the mechanism underlying the charge movement has not been fully clarified (Bezanilla, 2008).

Although the channels are activated (opened) by depolarizing the membrane, the C ↔ O equilibrium usually is strongly shifted toward O at $V_m = 0$ mV (Hodgkin and Huxley, 1952); that is, the depolarization removes a "stimulus" that normally keeps the channels closed.

The voltage-dependent shift in the C ↔ O equilibrium is given by

$$\frac{L^{C\to O}(V_m)}{L^{C\to O}(0)} = \exp\left\{\frac{z_a e V_m}{k_B T}\right\} \qquad (16)$$

where $L^{C\to O}(V_m)$ denotes the voltage-dependent C ↔ O equilibrium constant, and z_a denotes the gating valence (the charge movement associated with the C → O transition; z_a is positive for an outward movement of positive charge). The probability of the channel being open at a given voltage, V_m, thus becomes

$$W_O(V_m) = \frac{L^{C\to O}(0)}{L^{C\to O}(0) + \exp\{-z_a e V_m/k_B T\}} = \frac{1}{1+\exp\{-z_a e(V_m - V_{1/2})/k_B T\}} \qquad (17)$$

where $V_{1/2}$ is the potential at which $W_0(V_{1/2}) = 0.5$ (the midpoint potential for channel activation):

$$V_{1/2} = \frac{k_B T}{z_a e} \ln\{L^{C\to O}(0)\} \tag{18}$$

As is the case for the ligand-activated channels, the gating of voltage-activated channels is more complicated than summarized here: first, there are usually multiple closed states in the activation (Hodgkin and Huxley, 1952; Zagotta, Hoshi and Aldrich, 1994; Zheng and Sigworth, 1998); secondly, sustained depolarizations tend to promote transitions to one or more nonconducting, inactivated states (Figure 17.8) (cf. Yellen (2002)).

17.5.4.1 Voltage- and Ligand-Activated Channels

The distinction between voltage- and ligand activation is not always clear-cut. The function of many (if not all) voltage-dependent channels can be modulated by small molecules (including drugs and toxins) (Catterall *et al.*, 2007, see also Section 17.6) and the gating of ligand-activated channels can be modulated by changes in V_m (Magleby and Stevens, 1972). The most striking example of this dual regulation is the BK Ca^{2+}-activated potassium channels, which are both voltage- and ligand activated (Cox *et al.*, 2007; Magleby, 2001; Horrigan and Aldrich, 2002).

17.5.5
Mechanosensitive Channels

Mechanosensitive channels are activated by various mechanical stimuli (Sukharev and Corey, 2004; Markin and Hudspeth, 1995; Hamill and Martinac, 2001; Markin and Sachs, 2007), including changes in membrane tension (σ), which will shift the C ↔ O equilibrium when the cross-sectional channel area differ for the C and O states:

$$\frac{L^{C\to O}(\sigma)}{L^{C\to O}(0)} = \exp\left\{\frac{\Delta A\sigma}{k_B T}\right\} \tag{19}$$

where $L^{C\to O}(\sigma)$ denotes the tension-dependent, C ↔ O equilibrium constant, and $\Delta A = A_O - A_C$ where A_O and A_C denote the cross-sectional area of the open and closed state, respectively. The probability of the channel being open at a given tension, σ, thus becomes

$$\begin{aligned} W_O(\sigma) &= \frac{L^{C\to O}(0)}{L^{C\to O}(0) + \exp\{-\Delta A\sigma/k_B T\}} \\ &= \frac{1}{1 + \exp\{-\Delta A(\sigma - \sigma_{1/2})/k_B T\}} \end{aligned} \tag{20}$$

where $\sigma_{1/2}$ is the membrane tension at which $W_O(\sigma_{1/2}) = 0.5$:

$$\sigma_{1/2} = -\frac{k_B T}{\Delta A} \ln\{L^{C\to O}(0)\} \tag{21}$$

As is the case for ligand- and voltage-activated gating, the gating of mechanosensitive channels is more complicated than summarized here: changes in bilayer tension will cause changes in bilayer thickness (Evans and Needham, 1987), which in their own right may alter channel gating as has been demonstrated in the case of the gramicidin channel monomer ↔ dimer equilibrium (Goulian *et al.*, 1998); there are usually multiple closed, or intermediate conductance, states in the activation path (Anishkin, Chiang and Sukharev, 2005); and sustained stretch can promote transitions to one or more nonconducting, desensitized states [Figure 17.8; cf. Honore (2007)].

17.5.6
Other Mechanisms

Channel function also may be regulated by channel insertion into, or retrieval from, the target membrane – mediated by fusion, or budding, of vesicles in which the channels are incorporated in the vesicle membrane (Snyder, 2005). These regulatory mechanisms will not be discussed more here.

17.6
Regulation of Channel Gating

Ion channels, as other enzymes, are functionally regulated by covalent modification of the constituent protein [e.g. by phosphorylation (Hille, 2001) or oxidation (Barford, 2004)]; by small molecules that bind reversibly to the channel protein (Li *et al.*, 2005; Kaczorowski *et al.*, 2008; see also Ligand-Operated Ion Channels and Drug Design Strategies for Targeting G-Protein-Coupled Receptors); and by amphiphiles that bind the surrounding host bilayer (Andersen, 2008; Lundbæk, 2008). The mechanisms that underlie the regulation of globular proteins, therefore, also pertain to the regulation of ion channels (membrane proteins) (cf. Berg, Tymoczko and Stryer (2007), Chapters 7–10).

17.6.1
Ion Channels Are Special

Ion channels, however, are subject to additional regulatory mechanisms that do not pertain to globular proteins and which will be the focus here. These novel regulatory mechanisms arise from a key difference between ion channels (and other membrane proteins) and globular proteins, namely that the channels are inserted into and span the membranes' lipid bilayer. This is important because the conformational changes that underlie ion channel function involve the channels' TM domain and, therefore, perturb the packing of the adjacent lipids (Unwin, 1995; Perozo, Cortes and Cuello 1999; and Perozo *et al.*, 2002; cf. Figure 17.10], which incurs an energetic cost (Huang, 1986).

17.6.2
Hydrophobic Matching and Hydrophobic Coupling

The hydrophobic interactions between the channel's hydrophobic TM domain and the host lipid bilayer cause the bilayer to adapt to the channel's exterior, an adaptation called *hydrophobic matching* (Mouritsen and Bloom, 1984); channel conformational transitions that involve the channel/bilayer interface will alter this local bilayer perturbation, which incurs an energetic cost (Andersen and Koeppe, 2007, see also Chapter 10). For example, a transition between two different channel states, a closed (C) and an open (O) state, will be associated with a local bilayer deformation (Figure 17.10). The total free energy change for the protein conformational change $\Delta G_{\text{tot}}^{C\to O}$ therefore may be described as

$$\begin{aligned}\Delta G_{\text{tot}}^{C\to O} &= \Delta G_{\text{prot}}^{C\to O}\\ &\quad + \Delta\Delta G_{\text{bilayer, local}}^{C\to O}\\ &\quad + \Delta\Delta G_{\text{bilayer, bulk}}^{C\to O} \qquad (22)\end{aligned}$$

where $\Delta G_{\text{prot}}^{C\to O}$ is the energetic contribution from the protein conformational change *per se* (not related to the bilayer

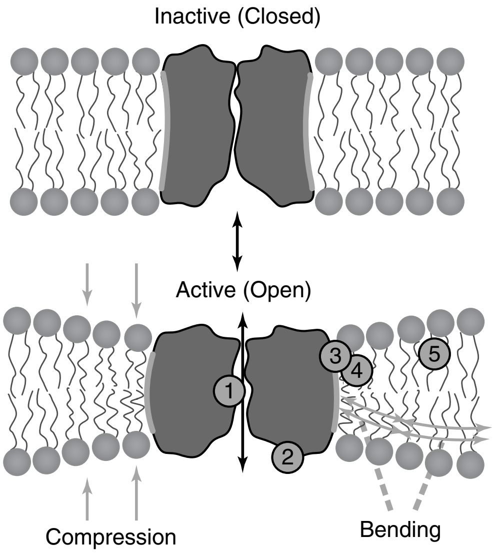

Fig. 17.10 Schematic representation of different, nonexclusive mechanisms by which one can regulate ion channel function. For simplicity, the conformational change underlying the C ↔ O is illustrated as a decrease in the length of the channel's hydrophobic TM domain, which is associated with a local deformation of the bilayer hydrophobic core (compression and bending of the two bilayer leaflets). (i) A drug may bind in, or very close to, the pore to block ion movement, (ii) a drug may bind to a site wholly formed by the protein to either inhibit or potentiate the channel function by altering the free energy difference between different channel states, (iii) an amphiphilic drug may bind specifically to a site composed of both the protein and the bilayer lipids, in which case its effects can involve also changes in the bilayer deformation energy associated with channel conformational changes, (iv) an amphiphilic drug may accumulate nonspecifically at the protein/bilayer interface to alter local lipid packing and thereby alter the bilayer deformation energy contribution to channel's conformational changes, and (v) an amphiphilic drug may adsorb at the lipid bilayer/solution interface to alter the lipid bilayer material properties and thereby the bilayer deformation energy associated with channel conformational changes

perturbation), $\Delta\Delta G^{C\to O}_{\text{bilayer, local}}$ is the energetic cost of the changes in local lipid packing ($\Delta\Delta G^{C\to O}_{\text{bilayer, local}} = \Delta G^{O}_{\text{bilayer, local}} - \Delta G^{C}_{\text{bilayer, local}}$, where $\Delta G^{C}_{\text{bilayer, local}}$ and $\Delta G^{O}_{\text{bilayer, local}}$ denote the energetic cost of local lipid packing at the channel/bilayer interface for C and O, respectively), and $\Delta\Delta G^{C\to O}_{\text{bilayer, bulk}}$ ($= \Delta G^{O}_{\text{bilayer, bulk}} - \Delta G^{C}_{\text{bilayer, bulk}}$) is the corresponding energetic cost of the bulk bilayer perturbation (Nielsen and Andersen, 2000). The equilibrium distribution between the two protein conformations is given by Andersen and Koeppe (2007) and Lundbæk (2006):

$$\frac{[\mathrm{O}]}{[\mathrm{C}]} = \exp\left\{-\frac{\Delta G^{C\to O}_{\text{tot}}}{k_B T}\right\} = \exp\left\{-\frac{\Delta G^{C\to O}_{\text{prot}} + \Delta\Delta G^{C\to O}_{\text{bilayer, local}} + \Delta\Delta G^{C\to O}_{\text{bilayer, bulk}}}{k_B T}\right\} \qquad (23)$$

The latter two energetic contributions vary as a function of the bilayer material properties [thickness, lipid intrinsic curvature, and the associated elastic moduli (Nielsen and Andersen, 2000)]; that is, there is *hydrophobic coupling* between the bilayer material properties and the function of bilayer-embedded proteins (ion channels) (Lundbæk, 2006).

17.7
Mechanisms of Drug-Induced Ion Channel Modulation

Small molecules (e.g. drugs) can regulate ion channel function by at least five different mechanisms (Andersen, 2008; cf. Figure 17.10). Specific examples of each of these mechanisms are listed in Table 17.5. The molecules may bind in – or near – the channel pore to physically occlude the lumen and block ion movement (see mechanism 1 in Figure 17.10 and Section 17.5.2). The molecules may regulate ion channel gating allosterically by binding to sites that are formed by the protein itself (as a conventional ligand binding site) to alter the $\Delta G_{\text{prot}}^{C\to O}$ contribution to $\Delta G_{\text{tot}}^{C\to O}$ (see mechanism 2 in Figure 17.10 and Section 17.5.3). These two mechanisms are general and apply also to globular proteins.

Because many drugs are amphiphiles [being hydrophobic and yet having some aqueous solubility (Lipinski *et al.*, 2001; Leeson and Springthorpe, 2007)], they will adsorb to the host lipid bilayer in addition to binding to the target channel (membrane protein). This means that they can regulate channel function by additional allosteric mechanisms. First, they can bind at the channel/bilayer interface to alter the $\Delta\Delta G_{\text{bilayer, local}}^{C\to O}$ (and also $\Delta G_{\text{prot}}^{C\to O}$) contribution to $\Delta\Delta G_{\text{tot}}^{C\to O}$ (mechanism 3 in Figure 17.10). Secondly, because the lipid bilayer material properties vary when amphiphiles adsorb to the bilayer/electrolyte interface (Ly and Longo, 2004), they can accumulate in the bilayer near the channel/bilayer interface and alter the $\Delta\Delta G_{\text{bilayer, local}}^{C\to O}$ contribution to $\Delta G_{\text{tot}}^{C\to O}$ (mechanism 4 in Figure 17.10), and they can adsorb to the bulk bilayer and alter the $\Delta\Delta G_{\text{bilayer, bulk}}^{C\to O}$ contribution to $\Delta G_{\text{tot}}^{C\to O}$ (mechanism 5 in Figure 17.10).

The common feature among mechanisms 2–5 in Figure 17.10 is that ligand binding, to the protein or the bilayer/solution interface, alters the contributions to $\Delta G_{\text{tot}}^{0}$ for the conformational transitions between different channel states (cf. Eq. (22)). At one extreme, mechanism 2 involves changes in $\Delta G_{\text{prot}}^{C\to O}$, a type of regulation that is shared by other (membrane-associated or water-soluble) enzymes and can be described by standard theories of ligand–receptor interactions (cf. Section 17.5.3). At the other extreme, mechanism 5 depends solely on changes in $\Delta\Delta G_{\text{bilayer, bulk}}^{C\to O}$, which are determined by the bilayer continuum material properties. Mechanisms 3 and 4 depend on changes in $\Delta\Delta G_{\text{bilayer, local}}^{C\to O}$ (and, in the case of mechanism 3, also $\Delta G_{\text{prot}}^{C\to O}$), which like $\Delta\Delta G_{\text{bilayer, bulk}}^{C\to O}$ are determined by the molecular composition of the bilayer immediately surrounding the channel. They also may involve local accumulation of molecules to diminish the energetic constraints on the local packing of lipid molecules adjacent to the channel – as deduced for polyunsaturated fatty acids (Bruno, Koeppe and Andersen, 2007). The key difference between these two mechanisms and mechanism 5 is that the magnitude

Tab. 17.5 Specific examples of mechanisms 1–5.

Mechanism	Channel	Molecule	Reference
1	Na_V	Tetrodotoxin	Hille (1975c)
1	Ca_V	ω -Conotoxins	Olivera *et al.* (1994)
1	K_V	Tetraethylammonium	Armstrong (1969)
2	Na_V	α- and β-Scorpion toxins	Catterall *et al.* (2007)
2	nAChR	ACh	Colquhoun and Sakmann (1985)
2	$GABA_A$	GABA	Kash, Trudell and Harrison (2004)
2’	$GABA_A$	Diazepam	Rudolph and Möhler (2004)
2’	nAChR	α-Bungarotoxin	Czajkowski, Kaufmann and Karlin (1993)
3	Kir	PIP_2	Hilgemann, Feng and Nasuhoglu (2001) and Suh and Hille (2005)
3	ENaC	PIP_2	Hilgemann, Feng and Nasuhoglu (2001) and Suh and Hille (2005)
3	TRPV	PIP_2	Hilgemann, Feng and Nasuhoglu (2001) and Suh and Hille (2005)
4 & 5	Na_V	Capsaicin	Lundbæk *et al.* (2005)
4 & 5	$GABA_A$	Docosahexaenoic acid*	Søgaard *et al.* (2006)
4 & 5	CFTR	Butanedione monoxime	Artigas *et al.* (2006)

Mechanism 2′ denotes the case in which the binding of one compound alters the affinity for the native ligand (e.g. GABA for $GABA_A$ and Ach for AChR).
PIP_2,phosphatidylinositol(4,5)bisphosphate.
* Docosahexanoic acid may exert its effect also through mechanism 3.

of $\Delta\Delta G^{C\to O}_{\text{bilayer, local}}$ also depends on the protein “shape.” The difference between mechanisms 3 and 4 is that the site of modulation in 3 is formed in part by the channel’s TM domain, which means that specific binding of the modulator to this site may occur (as well as a contribution from $\Delta G^{C\to O}_{\text{prot}}$).

A given molecule may affect ion channel function by any combination of these mechanisms. Mechanism 2 is the conventional allosteric mechanism. (Some drugs, such as diazepam, exert their action by binding to a site on the target and potentiating (or inhibiting) the action of another drug, such as GABA on the $GABA_A$ receptor; we denote this mechanism 2′, cf. Table 17.5.) To the extent that $\Delta\Delta G^{C\to O}_{\text{bilayer, local}}$ or $\Delta\Delta G^{C\to O}_{\text{bilayer, bulk}}$ are significant, on the order of $k_B T$, mechanisms 3–5 become important, and the lipid bilayer will be an allosteric regulator of ion channel (membrane protein) function (Andersen and Koeppe, 2007). Only mechanisms 1 and 2, and to a lesser extent 3, depend on specific, stoichiometric interactions with the channel; only mechanism 5 is altogether nonspecific. A challenge in future drug development becomes to identify the relative contribution of each of these mechanisms to a potential drug's overall effects – for then to optimize for the desired action. In this context, it is important that drugs with high affinity for the lipid bilayer/solution interface, relative to sites 1–3, may exert a significant part of their action through mechanisms 4 and 5, which make them promiscuous modulators of membrane protein function.

We finally note that molecules that reduce channel currents often are described as channel "blockers," whether or not the molecule in question actually enters the pore to occlude it. This is bad practice; the term blocker should be reserved only for mechanism 1, where there is a physical block or occlusion of the pore. Other molecules that reduce the channel-mediated ion movement are best described as channel "inhibitors." This terminology becomes important when a current reduction that is potentiated by repeated or frequent channel activation (as often is the case) is described as a "use-dependent block" – with the implication that mechanism 1 is involved. Any combination of mechanisms "1" to "5" may cause such an observation [cf. Lundbæk *et al.* (2005)], which is better described as "frequency dependent inhibition."

17.8
Conclusion

Ion channels constitute an important group of membrane proteins and are involved in many different biological functions. Because ion channels are generally efficient catalysts, they must be tightly regulated by mechanisms that control the channels' surface density and by mechanism that regulate the functional state of each individual channel. In addition to their physiological importance, the high turnover numbers allow for high-resolution measurements at the single-molecule level, which allow for detailed studies of how membrane protein function can be modulated/regulated. Finally, ion channels can be regulated – in addition to the mechanisms that have been established for globular proteins – by mechanisms that are unique for membrane proteins.

18.1
Introduction

Biological membranes are thin layers surrounding cells and their organelles, which define inside and outside of compartments. Their major components are lipids and proteins. Lipids are small amphiphilic molecules that are hydrophilic on one side and hydrophobic on the other side. When brought into contact with water, most lipids spontaneously form bilayer membranes. Our present picture of biomembranes stems from Gorter and Grendel (1925), Danielli and Davson (1935) and Singer and Nicolson (1972). The latter paper described the membrane as a two-dimensional bilayer of fluid lipids with proteins adsorbed or embedded. The Singer–Nicolson paper still dominates our present understanding of membranes, but it experienced some modifications. (Mouritsen and Bloom, 1984) proposed that the membrane is laterally heterogeneous as schematically shown in Figure 18.1. Here one sees domain formation and proteins that associate with different domains with different likelihoods.

The typical thickness of a lipid bilayer is about 5 nm. Thus, these are extremely thin layers as compared to the typical dimensions of cells (several 10 μm). Such membranes are flexible, heterogenous, and permeable. However, these properties depend not only on the conditions, for example on temperature, pressure, electrical field, pH, and salt concentration, but also on the presence of proteins and protein conformation. This basically means that the state of a biological membrane depends on all thermodynamic variables. These dependencies are discussed throughout this chapter. Thus, in this chapter, we focus rather on the properties of membranes as a whole than on the properties and functions of the individual molecules.

The composition of membranes is complex (see Section 18.2 for details). There are hundreds or even thousands of different lipid species and further thousands of different membrane proteins. The composition of membranes is different not only between different species, but also between different cell types of the same organism, and even between the membranes of different organelles within the same cell. Proteins act, for example, as catalysts and the importance of their role seems intuitively clear, while the role of the lipid membrane and the range of different lipid compositions is less obvious, and there is no agreement in the biophysical community yet on

what the purpose of the heterogeneity of the lipids precisely is.

Lipid membranes can undergo transitions from a rigid state into a liquid state (Section 18.3), where both the lateral order of lipid molecules and the order of the lipid hydrocarbon chains changes. In biological membranes, this occurs at temperatures that typically are slightly below body or growth temperature. Both states form two-dimensional membranes but their physical properties may be quite different. The lipid composition has an influence on membrane melting. The melting events in membranes lead to changes in the distribution of lipids within the membrane plane. In experiments, one finds regions of different composition and state. If they are of macroscopic dimensions, they are called *phases*; if they are on microscopic or nanoscopic scales, they are called *domains* or sometimes *rafts* in cell biology. The investigation of domain formation received much interest because of its putative influence on reaction cascades between proteins, and on diffusion processes within membranes. The melting transition in membranes is also interesting because of its influence on the elastic constants of membranes. In particular, at their melting temperatures, the membranes are very soft and easy to bend (Section 18.5). Related to this, the membranes also become very permeable for water, ions, and larger molecules (Section 18.7). Under some conditions, they may even propagate mechanical perturbations or pulses that resemble nerve pulses (Section 18.8).

18.2
Composition of Membranes

When discussing the composition of biological membranes, one has to distinguish proteins that are encoded in the genome, and the lipid composition that is not encoded in the genome. The latter rather adapts to the environmental conditions, partially by the control of membrane active proteins that display an activity depending on the physical state of the membrane.

18.2.1
Lipid Composition

There are hundreds of different lipids. What precisely counts as a lipid is only

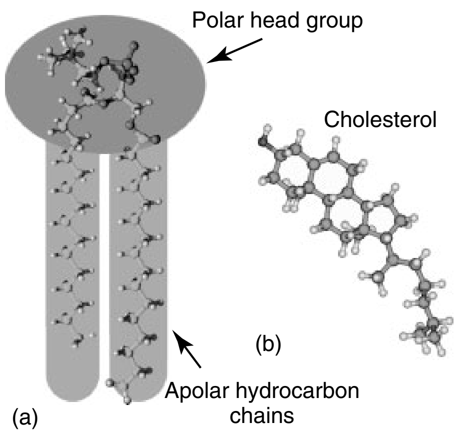

Fig. 18.2 (a) Dipalmitoyl phosphatidylcholine (DPPC) is a phospholipid molecule with zwitterionic polar head group and apolar fatty acid chains. (b) The steroid lipid cholesterol displays a quite different and much more rigid structure.

loosely defined. What lipids have in common is that they are small amphiphilic molecules that dissolve in membranes. By far the majority of these lipids are phospholipids with two hydrocarbon chains and a phosphate containing head group as shown in Figure 18.2a. However, one also finds minor fractions of lipids that only have one chain, or molecules of completely different structure as cholesterol (Figure 18.2a). This is a quite rigid molecule not forming membranes on its own. It is nevertheless a major component in some biological membranes, for example, in erythrocytes (Sackmann, 1995). One of the most obvious features being controlled by the chemical nature of the lipids is the melting point of the membranes, which is discussed in more detail in Section 18.3. Another property is the electrostatic potential of the membranes if the lipid head groups are charged.

18.2.1.1 Hydrocarbon Chains and Chain Length

Most lipids possess two hydrocarbon chains as shown in Figure 18.2. These chains vary in length from 12 to about 24 carbons. A second feature is the degree of unsaturation in the chain, that is, the number of double bonds in the chain. The chemical nature of the chains has a major influence on the melting temperatures of membranes as described in Section 18.3.

18.2.1.2 Head Groups

Lipids may also possess a variety of different polar head groups. Most lipids are phospholipids containing a phosphate group. About 40 mol% of the lipids in eucariotic cells are phosphatidylcholines (= lecithins) that are zwitterionic. They carry one negative and one positive charge in the physiological pH range. One example is shown in Figure 18.2. Another abundant heat group is the zwitterionic phosphatidylethanolamine that also contributes about 40 mol%. The rest are various other lipids that occur in smaller fractions, for example, the negatively charged phosphatidylserines, phosphatidylglycerols, phosphatidylinositols, and cardiolipins. Other lipids are sphingolipids and ceramides.

PC, phosphatidylcholines; PE, phosphatidylethanolamines; PS, phosphatidylserines; PI, phosphatidylinositols; SM, sphingomyelin; CL, cardiolipin.

18.2.2
Lipid Composition of Biomembranes

The lipid composition of membranes from different sources can be quite different. Examples are shown in Table 18.1. Human erythrocytes and rat liver plasma membranes, for instance, contain about 20 wt% cholesterol while rat liver mitochondria contain only 3 wt%. The phosphatidylcholine content of the endoplasmic reticulum is 48 wt% while the content in nerve myelin is only 11 wt%. Other examples can be found in Heimburg (2007) or Sackmann (1995). The differences in lipid composition between different cells, and even the organelles of the same cell are remarkable, but the reason is not completely understood.

18.2.3
Dependence on Thermodynamic Variables

It seems likely that the control of the thermodynamic parameters associated with the melting points of membranes (described in more detail in Section 18.3) belong to the most important features that are influenced by the lipid composition. This is a result of studying the lipid compositions of various organisms that live at conditions of variable temperature and pressure.

18.2.3.1 Growth Temperature

It has been shown that the lipid composition of cold-blooded organisms depends strongly on the ambient growth temperature. *Bacillus subtilis* bacteria show a largely altered lipid composition when grown at different temperatures (van de Vossenberg *et al.*, 1999). The composition of trout livers is very different in trouts caught in winter (water temperature ≈ 5 °C) and trouts in summer (water temperature ≈ 20 °C) (Hazel, 1979). In particular, the amount of unsaturated lipids is much higher in the livers of trouts in winter while the amount of saturated lipid is higher in summer. Unsaturated lipids have much lower melting temperatures than saturated lipids. It seems as if organisms adapt to their lipid compositions according to temperature in order to maintain a particular physical state of their membranes.

18.2.3.2 Growth Pressure

(DeLong and Yayanos, 1985) investigated barophilic marine bacteria. They found that the lipid composition of their membranes is highly dependent on growth pressure. Like temperature, pressure also has an influence on membrane melting. At high pressure, the melting point increases. (DeLong and Yayanos, 1985) found that the ratio of saturated to unsaturated chains linearly increases with ambient pressure.

18.2.3.3 Solvents and Anesthetics

Similar effects have been seen when *Escherichia coli* bacteria are grown in media containing solvents such as acetone or aniline (Ingram, 1977). Depending on the concentration of the solvents, one observes drastic changes in the composition of the membranes. In Section 18.3.1.3 it is shown that the adaptation of the lipid composition is accompanied by a change of the melting temperature of membranes.

18.2.4
Membrane Proteins

In contrast to the lipid structures, proteins are genetically encoded. The human genome contains about 30 000 genes that encode proteins, many of them being membrane proteins. Membrane proteins are much more difficult to crystallize than soluble proteins. Therefore, the number of known membrane protein structures is still small. Membrane proteins have various putative functions, but many are thought to be involved in transport processes across membranes. This includes the active transport of protons by the light driven rhodopsin, of sodium and potassium by the adenosine triphosphate (ATP)-consuming Na^+/K^+-ATPase, and passive transport by ion channel proteins, for example, Na^+-channel and K^+-channel (Figure18.3).

In this chapter, we focus on the physical properties of membranes as a whole rather than on the function of their components. The interested reader

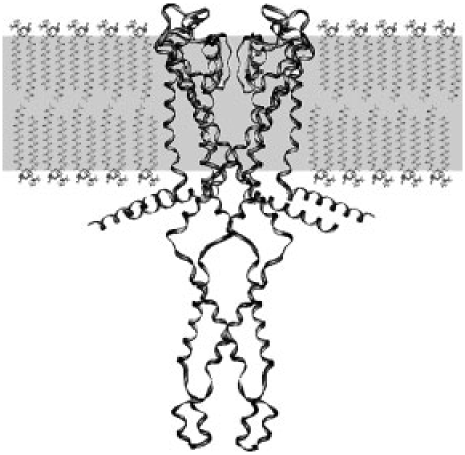

Fig. 18.3 The potassium channel protein spans through the lipid bilayer. Crystal structure of the protein from Cortes, Cuello and Perozo (2001).

may therefore, refer to other excellent publications on membrane proteins.

18.3
Membrane Melting

One of the important features of membranes is that they can melt. Melting processes are order transitions between two planar membrane phases or states that display different physical properties.

18.3.1
Chain Melting

The molecular origin of chain melting is shown in Figure 18.4. At low temperatures, lipid chains are ordered into an all-trans configuration (Figure 18.4, top left). At high temperatures these chains are disordered due to rotations around the C–C bonds within the lipid chains (Figure 18.4, top right). The membranes are in an ordered "gel" phase at low temperature while they are in a disordered "fluid phase" at high temperatures (Figure 18.4, center). The detailed nature of the phases involved in the melting process is described in more detail in Section 18.4.

18.3.1.1 Temperature Dependence and Heat Capacity

In the chain melting process, the molecules absorb heat (enthalpy) and the entropy increases due to the increase

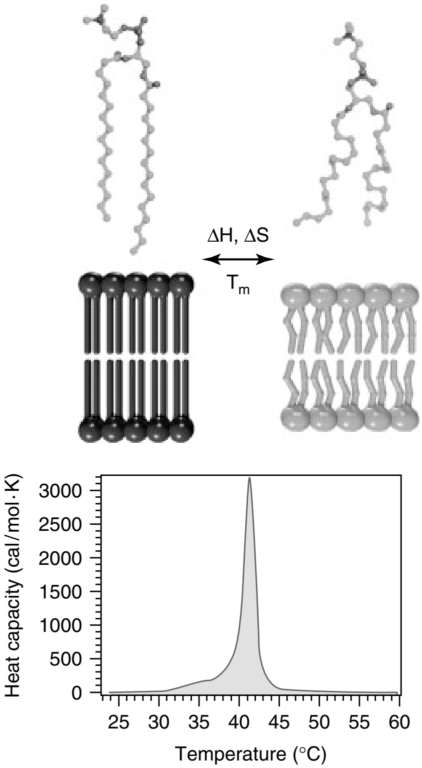

Fig. 18.4 Upon temperature increase, lipids undergo a melting transition where chains become unordered. This melting can be observed as a peak maximum of the heat capacity as measured in calorimetry.

in the number of possible chain configurations. The melting processes is cooperative, meaning that the lipids do not melt independently of each other. The absorption of heat is typically monitored by measuring the heat capacity, that is, the amount of heat absorbed per degree temperature increase. The heat capacity at constant pressure is defined by $c_p = (dH/dT)_p$. It is shown in Figure 18.4 (bottom). At the melting temperature, T_m, it displays a pronounced maximum.

18.3.1.2 **Pressure Dependence**

During the melting process, membranes also change their volume and area (Heimburg, 1998). As a rule of thumb the volume changes by about 4% and the area by about 25%. Owing to these changes, the melting temperature is pressure dependent. If one increases the hydrostatic pressure by about 40 bars, the melting temperature increases by 1°. Similarly, if one increases the lateral tension within the membrane, the melting temperature also changes. The latter effect can be studied on a Langmuir trough, where lipid monolayers are compressed by changing the film area while simultaneously monitoring the lateral pressure (Möhwald, 1990).

18.3.1.3 **Solvent Dependence**

There are other factors that change the melting temperature, for example, the partitioning of organic solvents in membranes. Typically, solvents do not dissolve well in the ordered low-temperature phase but dissolve quite well in the fluid phase. This gives rise to a lowering of the melting temperatures due to a well known effect called *freezing point depression*. As discussed in Section 18.9 this is likely to be related to anesthesia since most anesthetics resemble organic solvents.

18.3.1.4 **Voltage Dependence**

Membranes contain zwitterionic and charged lipids. The zwitterionic lipids have a head group that is an electric dipole. Thus, a monolayer of lipids possesses a strong dipole potential across that layer, which can be of the order of 500 mV (e.g. Pickard, Sehgal and Jackson (1979)). Upon area changes in a monolayer experiment, one finds that the lateral pressure changes in close relationship to this dipole potential. This implies that similar to the change in pressure, voltage changes can induce a transition in the lipid monolayers. Since a membrane consists of two monolayers, these potentials partially compensate. In the presence of charged lipids, the membranes additionally possess a net electrostatic potential that is discussed in Section 18.6.

18.3.1.5 **Dependence on Membrane Proteins**

As already mentioned in Section 18.2.4, many proteins are embedded into or absorbed on membranes. This also has an influence on melting processes (Zhang *et al.*, 1995). Some proteins shift transitions to higher temperatures, for example, the band 3 protein of erythrocytes (Morrow *et al.*, 1986) while others shift it rather to lower temperatures, for example, cytochrome b5 (Freire *et al.*, 1983). For integral proteins, the shift is related to the hydrophobic matching between proteins and lipid bilayer thickness (Mouritsen and Bloom, 1984).

18.3.2
Melting in Biomembranes

Most of the above has been investigated in model membranes or monolayers made of synthetic lipids. However, all of it gains biological relevance due to the fact that biological membranes also possess such melting transitions of their membranes, typically slightly below body temperature. This can be seen in Figure 18.5. Here, heat capacity profiles of native *E. coli* membranes are shown. The two traces are from bacteria grown at two different temperatures, one at 37 °C and the other one at 15 °C, respectively. Numerous peaks can be seen in these traces. The membrane melting peaks are shaded in gray. The other peaks represent the unfolding of proteins at higher temperatures. The membrane melting peak occurs at lower temperature for bacteria grown at 15 °C than for those grown at 37 °C. The bacteria adapt their membrane lipid compositions such that the melting point of the membranes is always below growth temperature. That the lipid composition responds to the changes in the environment has already be described in Section 18.2.

18.4
Phases and Domains

The thermodynamics of ensembles of molecules allows for the formation of quite different phases. If the conditions are right several phases may coexist. This happens in temperature, pressure, or concentration intervals well defined by the thermodynamic parameters of the system. The graphical representation of the coexistence of such phases is called a it phase diagram (cf. Figure 18.7).

The most common phases found in artificial and biological membranes are the solid ordered (SO) phase, the liquid ordered (LO) phase, and the liquid

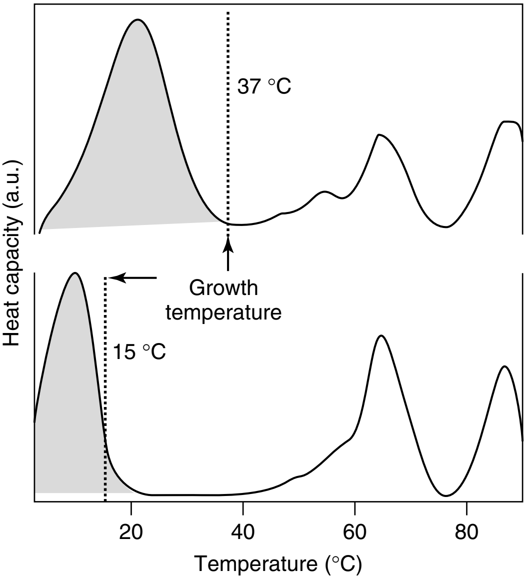

Fig. 18.5 The native cell membranes of *E. coli* bacteria also display chain melting of their membranes at temperature slightly below growth temperature (shaded gray). The lipid membrane melting peaks adapt to the growth temperature (dotted line). The peaks above growth temperature are protein unfolding peaks. Their position does not depend on growth temperature.

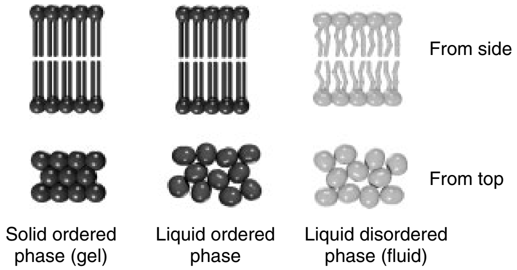

Fig. 18.6 The three most common membrane phases seen as cross sections and from top: solid ordered (SO), liquid ordered (LO) and liquid disordered (LD) phases. The first two phases (SO and LO) are low enthalpy phases, while the LD phase is a high enthalpy phase mostly existing at high temperatures.

disordered (LD) phase (Figure 18.6). "Solid" means that the lipids arrange on a (typically triangular) lattice in the membrane plane while "liquid" indicates the loss of lateral packing (Figure 18.6, bottom). The attributes "ordered" and "disordered" indicate the internal order of the lipid chains (Figure 18.6, top). The transition between ordered and disordered states is linked to the uptake of significant amounts of enthalpy (i.e. heat), as already described in Section 18.3 (Figure 18.4). The SO phase is also often called the *gel phase* and the trivial name of the LD phase is the "fluid phase." In the literature one often finds those trivial names of the phases.

Typically, the different phases differ in their physical properties. For instance, they may display very different elasticities, auto-diffusion constants or electrostatic potential. Under most circumstances, biological membranes seem to exist in the LD phase. Owing to the proximity to melting transitions, however, this can be fine tuned by the organism.

18.4.1
Gibbs Phase Rule

In a lipid mixture like the biological membrane, one may find more than the three phases mentioned above. For instance, one could have two LD phases coexisting.

Let us assume we have K lipid (or protein) components, and P phases. Of course, one has always at least one phase, that is, $P \geq 1$. Further, we introduce the number of degrees of freedom, F, that indicates how many variables can be changed independently of each other. Such variables are the concentrations of the different membrane component and the temperature. The number of degrees of freedom must always be positive, that is, $F \geq 0$.

There is a famous thermodynamic rule about how many different phases can coexist for a given number of components and degrees of freedom that is called *Gibbs phase rule*. At constant pressure it is given by:

$$F = K - P + 1 \quad \text{Gibbs' phase rule} \qquad (1)$$

Let us give a simple example for this. In a binary lipid mixture as described in Figure 18.7 one has two components, that is, $K = 2$. Let us now check all possibilities:

$$\begin{aligned} P = 1 &\rightarrow F = 2 \\ P = 2 &\rightarrow F = 1 \\ P = 3 &\rightarrow F = 0 \end{aligned} \qquad (2)$$

The first case indicates that one has only one phase, and one can vary both the concentration of the second component and

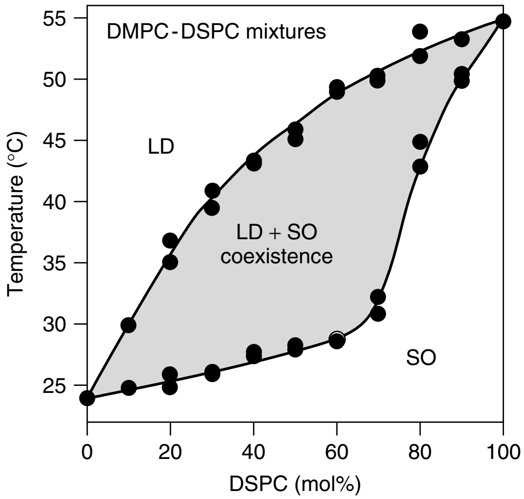

Fig. 18.7 Phase diagram of a simple binary lipid mixture. The gray-shaded region indicates the regime of temperature and concentration where a LD (gel) and a LD (fluid) phase coexist. Adapted from Hac *et al.* (2005).

the temperature freely without leaving the one-phase region. The second case indicates that one may have two different phases coexisting. However, when one of the variables (e.g. temperature) is varied, the second variable (concentration of the components in the two phases) is automatically determined and can not be varied freely. The last case in Eq. (2) indicates that there may be points (with both defined temperature and composition) where three phases may coexist.

18.4.2
Phase Diagrams

An example for a simple phase diagram is shown in Figure18.7. It represents the mixture of two synthetic lipids dimyristoyl phosphatidylcholine (DMPC), and distearoyl phosphatidylcholine (DSPC) in aqueous environment. The two variables in this system are temperature and the fraction of DSPC. These two variables represent the two axes. In the gray shaded region SO and LD phases coexist. At a given temperature, the composition of the two phases are given by the lines in the phase diagram (for details see Lee (1977)). Above the upper line (liquidus line), the whole membrane is in the LD (fluid) phase, while it is in the SO (gel) phase below the lower line (solidus line).

Biological membranes, however, consist of hundreds of components, which are the different lipids, the membrane proteins, and the many small molecule components. What is immediately clear from the above is that in a biological membrane with several hundred components, one may also have many different phases coexisting. For $K = 100$ one may in principle find up to 101 coexisting phases ($P = 101$). Thus, the thermodynamic behavior of such membranes may be very complex, and it may be practically impossible to unravel the detailed behavior of such complex mixtures. Nevertheless, clearly such phase coexistence is present in biological membranes and must strongly influence their behavior. Therefore, to make general statements on the physical behavior of biomembranes, one may wish to find general relations that do not require the detailed knowledge of the phase diagram. Such relations exist and will be outlined in Section 18.5.

18.4.3
Domain Formation

The concept of a phase is a strictly theoretical one assuming, for instance, that the system under consideration is infinitely big, and that the phases are separated from each other (i.e. their interface can be neglected). Both assumptions are not quite true for biological membranes. Cells are relatively small (on the order of 10^9 lipids) and phases cannot be macroscopically separated. Instead, one typically obtains finite size domains that interact at their boundaries. What can be concluded from the above is that both artificial membranes are made of lipid mixtures, and biological membranes must display the coexistence of many domains of different physical properties.

18.4.3.1 Domain Formation in Artificial Membranes and Monolayers

Domain formation in artificial systems is actually quite easy to observe. Already in the early 1980s, domains were described in monolayer films (e.g. Weis and McConnell (1984); Möhwald (1990)). The first demonstration of domain formation on bilayer membranes was from Korlach *et al.* (1999). In Figure 18.8 (left) we show a confocal fluorescence microscopy image of a giant vesicle (Ø ≈30 μm) made of a lipid mixture of dilauroyl phosphatidylcholine (DLPC) and dipalmitoyl phosphatidylcholine (DPPC) measured at room temperature. According to the phase diagram of this lipid mixture it should display phase coexistence at room temperature. This can be seen as dark and light grey domains that have been labeled with two different fluorescence markers with affinity for the two different phases. Dark grey domains are in the SO phase, while the light grey regions are LD phases. Such domains are obviously rather big, that is, of order of 5–10 μm.

18.4.3.2 Domain Formation in Biological Systems

Domain formation in biological membranes is much more difficult to monitor. In the 1990s, several authors proposed the existence of domains called *rafts* (Simons and Ikonen, 1997; Brown and London, 1998; London, 2002; Edidin, 2003b; Edidin, 2003a). They are thought to be rich in cholesterol, sphingolipids, and some GPI-anchored proteins that are in the LO phase (Figure 18.9). The physical evidence for such domains in real biomembranes is relatively weak. If they exist, they seem to be smaller than the resolution of a light microscope (<200 nm). Further, owing to the many

different components of biological membranes there is no need to constrain the concept of domain formation to particular domain compositions. There may be domains of all kinds of compositions, for example, protein clusters (already shown in the famous paper by Singer and Nicolson (1972)), but also SO and LD domains. One of the nicest demonstrations of domains in cells to date is from Gaus *et al.* (2003) in fibroblast cells shown in Figure 18.8 (right).

18.5
Curvature and Elastic Constants

Membranes are typically not flat rigid sheets but often display curvature when they form vesicles and organelles. They are soft and display both fluctuations in area and curvature. Further, when membranes are asymmetric they may curve spontaneously.

18.5.1
Principle Curvatures

Bending can be characterized by its radius of curvature, R, or its curvature, $c = 1/R$ (Figure 18.10). Since the surface has two dimensions one typically deals with two principle curvatures, c_1 and c_2, that may be different.

To curve the membrane one has to provide free energy. The free energy density of a membrane, g, is given by a famous formula by Helfrich (1973):

$$g = \frac{1}{2} K_B \left(c_1 + c_2 - c_0\right)^2 + K_G c_1 c_2 \quad (3)$$

This equation contains three material constants that have to be determined

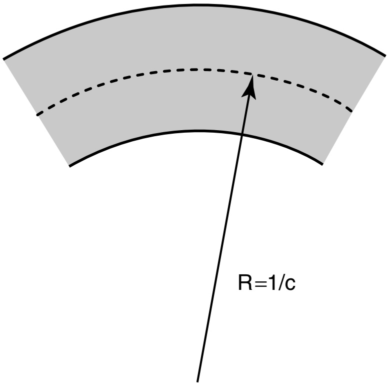

Fig. 18.10 Curvature and radius of curvature for a bend membrane.

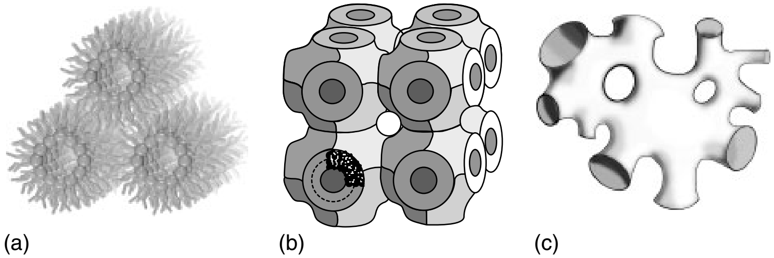

Fig. 18.11 Lipid phases with different curvatures. (a) Inverse hexagonal phases (from Heimburg (2007)), (b) Cubic phase (adapted from Lindblom and Rilfors (1989)). (c) Sponge phase (from Heimburg (2007)).

experimentally: K_B is the bending modulus, K_G is the Gaussian curvature modulus, and c_0 is the spontaneous curvature. The spontaneous curvature indicates the equilibrium curvature of the membrane. It mainly depends on the asymmetry of the membrane, for example, different lipid and protein compositions in the two opposing monolayers of the membrane, but also on electrostatic potential differences, pH differences, and so on.

18.5.2
Curved Phases

There exist various curved lipid phases.

The inverse hexagonal phase (Figure 18.11a) is not a membrane phase. It is formed due to the spontaneous curvature of the monolayers. There has been quite some discussion on whether the potency of biological membranes to form such phases may be linked to biological function (Toombes *et al.*, 2002).

The cubic phase (Figure 18.11c) resembles a periodic three-dimensional lattice of vesicles that are connected. It is a bicontinuous bilayer structure with no inside and outside. It displays saddle-point structures. These are the geometries where the two principle curvatures, c_1 and c_2 have opposite sign.

The sponge phase (Figure 18.11c) has the same topology compared to the cubic phase, but it does not display any periodic regularity.

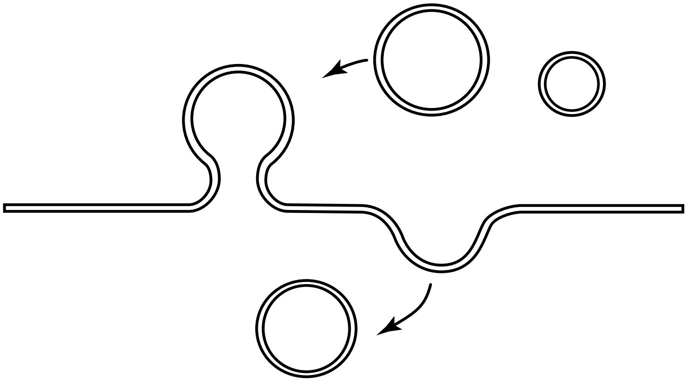

Fig. 18.12 Fusion and fission events as in endocytosis and exocytosis (adapted from Heimburg (2003)) that involve changes in local curvature.

Figure 18.12 shows the biological processes of endocytosis and exocytosis, that is, fusion and fission of vesicles and membranes. They obviously display a very similar saddle-point geometry at the site of fusion as the cubic and the sponge phases. This triggered the interest in such membrane phases (Lohner, 1996; Toombes *et al.*, 2002).

18.5.3
Elastic Constants

The volume compressibility is the function that indicates how much the volume changes when the pressure is increased by an incremental amount. Very compressible substances display a large change in volume when the pressure increases. The area compressibility is the respective function that indicates how much the area changes upon changes in lateral pressure or surface tension.

The curvature elasticity is the inverse of the curvature modulus as defined in Eq. (3). (Evans, 1974) has shown that the curvature elasticity is linearly related to the lateral compressibility.

18.5.4
Temperature and Pressure Dependence of Elastic Constants

The elastic constants are actually not real constants. They themselves depend in a sensitive manner on the thermodynamic variables, for example, on temperature, pressure, and so on. In particular, it has been shown by Heimburg (1998) and Ebel, Grabitz and Heimburg (2001) that all the elastic constants depend in a simple manner on the heat capacity of the membrane that assumes high values in the transitions of membranes (see Figures 18.4 and 18.5). This means that within transitions, membranes are very elastic. They are soft, easy to bend, and easy to compress. Since biological membranes display such transitions close to body or growth temperature, this is of quite high significance. Everything that is related to the elastic constants will respond very sensitively to changes in temperature and other variables like pH, calcium content, and so on. This includes membrane fusion events as well as the spontaneous formation of pores in the membrane as shown in Section 18.7. We further show in Section 18.8 that close to such transitions one obtains the possibility to propagate stable pulses along cylindrical membranes.

18.6
Electrostatic Potential

On average, about 10% of all lipids are negatively charged. As mentioned in Section 18.2, the relative amount of negative charge is very different depending on the particular organelle of a cell. Especially charged are the membranes of mitochondria that contain up to 20% cardiolipin that have two negative charges each. Further, the charges often distribute asymmetrically such that the inner membranes of cells and organelles are more charged (Rothman and Lenard, 1977; Rothman and Kennedy, 1977).

18.6.1
Ionic Strength Dependence

The electrostatic theory of surfaces originates from Gouy and Chapman (see, e.g. Jähnig (1976)). It describes how the electrostatic potential on surfaces depends on the charge density and on the ionic strength of the salt solution. For membranes one finds that the electrostatic potential decays fast as a function of the distance from the membrane. The characteristic decay length is called the *Debye length*. For a 100 mM solution of NaCl it is 0.97 nm. For 10 mM NaCl it is about 3.1 nm and for 1 mM it is 9.7 nm. Close to the membrane, the Na^+ concentration

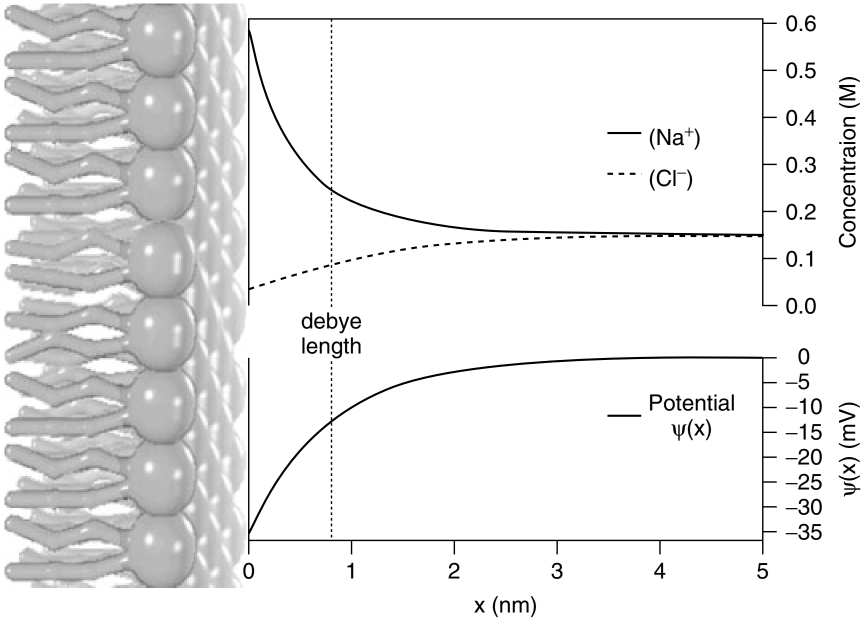

Fig. 18.13 Distribution of positive (Na^+) and negative ions (Cl^-), and magnitude of the electrostatic potential, Ψ, as a function of distance from a membrane containing acidic lipids, calculated for a NaCl concentration of 150 mM. From Heimburg (2007).

is increased, while the Cl^- concentration is reduced (Figure 18.13).

18.6.2
Dependence on Charged Lipid Concentration

Naturally, the electrostatic potential at a membrane surface also depends on the number of charged molecules the form the membrane. For the ionic strength conditions that are normally found in biology, the surface potential is just proportional to the charge density on the surface and inversely proportional to the square root of the ionic strength.

18.6.3
Dependence on Bound Proteins

Proteins also carry charges. Many soluble proteins are positively charged and therefore interact with negatively charged lipid membranes. One example is cytochrome c, a protein from the respiratory chain in mitochondria, with a net positive charge of about 4. It binds to the highly charged mitochondrial membranes and reduces the overall electrostatic potential.

18.7
Permeability

Many biology textbooks state that lipid membranes are impermeable to water, ions and small molecules. Although this seems intuitive because the inner core of a membrane is made of hydrocarbons, this is not quite correct. The lipid layers are very thin and due to fluctuations in molecular there is always some finite likelihood that spontaneous pores are formed. This likelihood is dramatically increased in the phase transition temperature regime of lipid membranes, that is, slightly below body temperature for biomembranes (Papahadjopoulos *et al.*, 1973); (Nagle and Scott, 1978). Figure 18.14 shows the permeability of artificial membranes for a

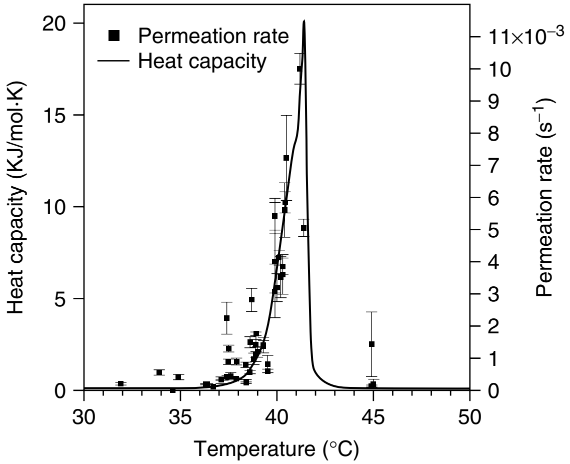

Fig. 18.14 Permeability of a lipid vesicles for a fluorescent dye as a function of temperature compared to the melting profile (Blicher *et al.*, 2009).

fluorescence dye as a function of temperature compared to the heat capacity. One can recognize that the permeability is closely related to the heat capacity.

18.7.1
Protein Ion Channels

Since the permeability of lipid membranes is thought to be small, most of the permeation events through membranes have been attributed to proteins that form pores or ion channels. In patch clamp or black lipid membrane (BLM) measurements on finds quantized ion currents through the membrane indicated localized events. Figure 18.15b shows the first of such traces recorded in the presence of the acetylcholine receptor protein published by Neher and Sakmann (1976). Both scientists received the Nobel prize in 1991. The currents occur in discrete steps that can be seen in the histogram at the right hand side. For a detailed description of ion channel proteins see Hille (1992).

18.7.2
Lipid Ion Channels

As already seen in Figure 18.14 the lipid membranes are also permeable to molecules if they are close to their phase

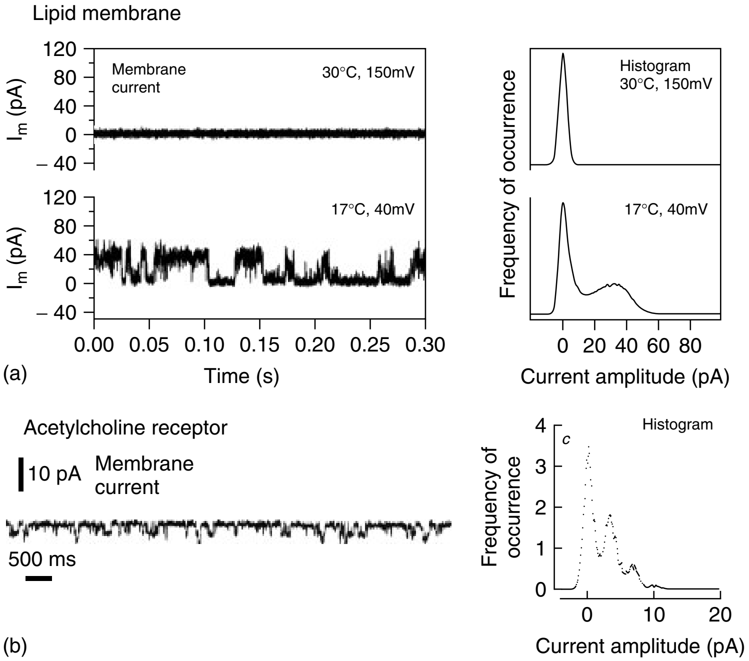

Fig. 18.15 *Microscopic permeability of membranes in the presence and absence of proteins. (a) Spontaneous ion currents through a synthetic black lipid membrane at its phase transition (17°C). Above its transition at 30°C the currents disappear (Fidorra, 2007).* (b) Spontaneous ion currents through a biological membrane in the presence of the acetylcholine receptor adapted from the original paper of Neher and Sakmann (1976).

transition temperature. In patch clamp or BLM measurements one finds quantized ion currents through the membrane. This can be seen in Figure 18.15a for a lipid mixture with transition maximum at 17 °C. The currents at the transition temperature resemble those seen in the biological membrane describe above. At 30 °C the currents disappear. This effect is not as well known as the protein conductance but has been described by a number of authors in the literature (e.g. Antonov *et al.*, 1980; Kaufmann and Silman, 1983b; Kaufmann and Silman, 1983a; Gögelein and Koepsell, 1984; Antonov *et al.*, 2005; Blicher *et al.*, 2009). Protein ion channels are always embedded in membranes. Biological membranes are close to their transition temperature where they can also show quantized channels due to events in the lipid membrane. Therefore, it does not seem straight-forward how to distinguish between the two events.

18.8
Pulse Propagation

Nerve cells form long membrane cylinders that are called *dendrites* or *axons*. Along these cables one finds the propagation of voltage pulses that are called *action potentials*. However, mechanical pulses can also travel along nerve membranes. It turns out that these two seemingly different events may well be caused by one single phenomenon.

18.8.1
Nerve Pulses

Action potentials have been described by Hodgkin and Huxley (1952) (Nobel prize 1963). Their theory is based on the existence of voltage-gated ion channels (in particular of sodium and potassium channels, see Figure 18.3). It is an electrical theory in which the lipid membrane serves as a capacitor and the ion channel proteins are electrical resistors. The resulting differential equation has the shape of a propagating voltage pulse very similar to that observe in real nerves. Since it is a purely electrical model, it does not contain and describe any changes in other variables, for example, heat, volume, thickness, and area.

18.8.2
Soliton Propagation

Biological membranes are slightly above their transition temperature where both the elastic constants and the permeability change drastically. (Heimburg and Jackson, 2005) showed that under these conditions stable mechanical pulses (called *solitons*) can travel along membranes. Since membranes possess both dipole potentials and electrostatic potentials, these mechanical pulses are accompanied by changes in voltage. The properties of such pulses are based on reversible physics. Area, thickness, and voltage of the membranes change during the pulses. Since the events are reversible, the process is isentropic, that is, no heat is dissipated during the pulse. During the pulse, all variables change that are associated to the phase transition in membranes. The free energy necessary to generate a pulse is given by its distance to the phase transitilidocaineon.

18.8.3
Reversible Heat

A problem for the Hodgkin–Huxley model is the experimental fact that no heat is dissipated during the nerve pulse (Abbott, Hill and Howarth, 1958; Howarth, Keynes and Ritchie, 1968; Ritchie and Keynes, 1985). Since currents flow through resistors (the ion channels), heat production would be expected during the action potential. Instead, one first finds a phase of heat liberation followed by a phase of heat reabsorption. This finding is rather in agreement with a reversible electromechanical pulse as described by the soliton theory.

18.8.4
Mechanical Changes

Nerves change their dimensions during the action potential. Tasaki and coworkers found that during the action potential the nerves change their thickness by about 1 nm (e.g. Iwasa and Tasaki (1980); Iwasa, Tasaki and Gibbons (1980); Tasaki and Byrne (1990) and that nerves also get shorter upon excitation (Tasaki, Kusano and Byrne, 1989)). Thus, in addition to the electrical phenomena mechanical changes also exist during nerve pulses.

18.9
Anesthesia

Anesthesia is a phenomenon caused by a number of small molecules that partition in the biological membrane. For more than 100 years, it is known that the effectiveness of anesthetics is proportional to their solubility in olive oil (that has the properties of the membrane interior). This rule is known as the *Meyer–Overton rule* (Overton, 1901). It holds over several orders of magnitude ranging from laughing gas, N_2O, and over halothane to lidocaine. Even the noble gas xenon is an anesthetic. This excludes any specific binding to macromolecules (e.g. proteins) if one is searching for a generic explanation of anesthesia. It has also been known for a long time that anesthetics cause a lowering of phase transition temperatures (Trudell *et al.*, 1975; Kharakoz, 2001; Heimburg and Jackson, 2007b). This has already been discussed in Section 18.3.1.3. There are strong indications that the effect of anesthetics is related to this finding. As shown in Section 18.3.1.2, phase transitions are pressure dependent. While pressure increases transitions, anesthetics lower them. It has in fact been found that pressure reverses the effect of anesthesia (Johnson and Flagler, 1950). In the context of the soliton theory (Section 18.8.2), anesthetics increase the free energy necessary to generate an electromechanical pulse (Heimburg and Jackson, 2007a; Heimburg and Jackson, 2007b). There is no obvious connection between the Hodgkin–Huxley model and anesthesia, but there are attempts to relate the action of anesthesia to specific binding to in channel proteins.

19.1
Introduction

Single molecule detection and chiral spectroscopy are two powerful tools within Raman spectroscopy (RS), and they have been combined into one tool in order to provide chiral information obtained at the single molecule level. This had first been predicted by (Efrima, 1983, 1985); however, the lack of an experimental evidence has until recently been dominant in the field. It is worth mentioning that the experimental results, which have been published and those which are discussed here, cannot yet be considered as results of single molecule measurements, in that they provide knowledge about the average for a number of molecules that contribute to the measured signal. A single molecule measurement should naturally concern a detection of 1.6×10^{-24} mol of an analyte. This requires a very small interaction cross section, an optical property that defines the ratio of the intensity of the incident to the scattered light. So far fluorescence emission has been the most utilized tool for single molecule detection (Morner, 2006), where a typical cross section of a chromophore can be 10^{-16} cm^2/molecule, a limit that is known to define single molecule detection. Raman scattering (RS), an alternative tool, which has the capability of providing more information than fluorescence, especially at room temperature, could not be used when information on a single molecule is desired. This is because the scattering cross section of RS is about 10^{-30} cm^2/molecule. However, during the last three decades and after the discovery of another Raman tool, known as *surface-enhanced Raman scattering* (*SERS*), this has become an alternative to fluorescence, especially when the resonance effect, known as *surface-enhanced resonance Raman scattering* (*SERRS*), takes place at the same time. In such conditions, the cross section can approach the limit for detecting a single molecule (Nie and Emory, 1997). In general, there are relatively few reports on single molecule detection, including fluorescence, and in these reports one finds that the dye rhodamine is the most common sample from which the results were reported, with only very few reports on biomolecules, for example, porphyrin (Bizzari and Cannistrato, 2002), enkephalin (Kneipp *et al.*, 2004) and adenine (Koo *et al.*, 2004).

Another Raman tool, which is sensitive to molecular chirality, is Raman optical activity (ROA) from which

Handbook of Molecular Biophysics. Methods and Applications. Edited by Henrik G. Bohr.
Copyright © 2009 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 978-3-527-40702-6

knowledge about the molecule structure and stereochemistry can be obtained. However, the ROA signal intensity is very weak, and its combination with a single molecule technique is desirable. In the following sections, ROA, SERS, and the attempts at combining them, both theoretically and experimentally, have been discussed.

19.1.1
Overview of ROA

Chiral Raman spectroscopy, known as *Raman optical activity (ROA)*, is a technique that has mostly been employed for molecular studies owing to the fact that ROA spectra provide information about the studied molecule in solution, thus, it is extremely useful for bioanalysis in native environments. Similar to the Raman effect, ROA is a result of interaction between monochromatic electromagnetic (EM) radiation, usually in the visible region of the EM spectrum, and a biomolecule (Barron, 2004). However, it differs from Raman spectroscopy as circular polarized light is used, and the difference in intensity of scattering of the right- and left scattered light represents the ROA. Therefore, ROA can provide information on the molecular optical activity.

The optical activity effect has been known for a long time now, being first observed by Dominique Arago (1811); however, the discovery of stereoisomers and the formulation of chirality were introduced by Lord Kelvin (1904) as follows: *"I call any geometrical figure or group of points chiral, and say that it has chirality if its image in a plane mirror, ideally realized, cannot be brought into coincidence with itself."*

Using Raman spectroscopy the first ROA theory was formulized in 1969, in which a general theory of the polarization characteristics of Rayleigh, the elastic scattering, and Raman scattered light from chiral molecules based on a new interference mechanism between light waves scattered via the polarizability and optical activity property tensors was presented by Atkins and Barron (1969). In this work they were able to predict that the small difference in the scattered intensity in the right- and left-circular polarized incident light can be detected, and it hence represents a fingerprint of a chiral molecule. Barron and Buckingham succeeded in 1971 in incorporating the contribution of the electric dipole-magnetic dipole optical activity tensor to Raman scattering (Barron and Buckingham, 1971), and they defined in their work the experimental parameter of the dimensionless circular intensity difference (CID, or Δ) as follows:

$$\Delta = \frac{(I^R - I^L)}{(I^R + I^L)} \tag{1}$$

where I^R and I^L are the scattered intensities in right- and left-circular polarized incident light, respectively. As Eq. (1) indicates, the CID can be very small, and in fact this intensity is three to four orders of magnitude lower than the conventional Raman scattered intensity, equal to $(I^R + I^L)$, for the same molecule. Therefore, better tools, including stable monochromatic light sources, high efficiency filters to define the monochromatic wavelength, optical components for ensuring the circular polarization (CP) of the beam, and high sensitive detectors, were all required.

The technical requirements have made measurements difficult, at least until recently, and limited the use of ROA to a handful of laboratories worldwide, with the first reliable spectrum being published in 1973 (Barron, Bogaard and Buckingham, 1973) and confirmed two years later (Hug *et al.*, 1975). In spite of these requirements, ROA has proven to be an incisive probe of stereochemistry and molecular structure. Numerous studies by the Barron group at the University of Glasgow pioneered the use of ROA for conformational analysis of proteins, nucleic acids, viruses, and glycoproteins (Barron, 2004; Blanch, Hecht and Barron, 2003, more recent references). This body of work in conjunction with the introduction of the first commercial ROA spectrometer by BioTools Inc. in 2001 has generated the recent increase in the number of ROA researchers and the scope of applications. For a thorough description of ROA theory, results, and applications, the reader is directed to other reviews (Barron *et al.*, 2004).

19.1.2
Overview of SERS

At the same time as ROA became reliable, another phenomenon, known as *surface-enhanced Raman scattering (SERS)*, in Raman scattering was discovered (Fleischmann, Hendra and McQuillan, 1974; Jeanmaire and Van Duyne, 1977; Albrecht and Creighton, 1977). This effect takes place when a molecule is adsorbed on, or is in the vicinity of, a metallic nanoparticle, typically Ag, Au, or Cu. Consequently, an enhancement in the scattered field takes place. This effect was very soon adapted by most research laboratories within the Raman community because in general it provides, in spite of the difficulty of having stable nanoparticles, an enhancement of minimum 10^3 to 10^7 of the scattered Raman intensity (Kerker, 1990). The SERS effect has since its discovery been widely studied and the enhancement can be attributed to the EM mechanism as well as to the chemical (Ch) mechanism, and the signal can be defined as follows:

$$\phi^{\mathrm{SERS}} = \frac{I_I}{\hbar\omega_I}\sigma^R \sum_{i=1}^{N} M_i^{\mathrm{EM}} M_i^{\mathrm{Ch}} \qquad (2)$$

where I_{I} and ω_{I} are the intensity and the angular frequency of the incident beam, respectively, σ^{R} the Raman cross section (a parameter which is proportional to the square of the first polarizability derivative for a vibrational transition and the fourth power of the scattering frequency), and M_i^{EM} and M_i^{Ch} are the enhancements due to the EM and Ch contributions, respectively. This giant enhancement has been of great importance especially in biomolecular studies because within this effect the cross section is increased to the level of fluorescence, and on the other hand, and most importantly, as the intensity is proportional to the number of molecules taking part in the scattering, SERS enables studies of molecules at lower concentration compared to instant ordinary Raman scattering. That is, molecules at lower concentration under enhancement conditions can now provide the same intensity of signal, by keeping other experimental parameters constant. This can be expressed as follows:

$$P_{\mathrm{SERS}}(\nu) = NI(\nu)|A(\nu_L)|^2|A(\nu_s)|^2\sigma_{\mathrm{ads}} \qquad (3)$$

where N is the number of molecules, $I(\nu)$ the intensity of the excitation laser, $A(\nu_{\mathrm{L}})$ and $A(\nu_{\mathrm{S}})$ the field confinement of the optical coefficients related to the incident and the scattered light frequency, respectively, and σ_{ads} is the adsorption cross section. The field enhancement factor depends also on the distribution of the colloids in the measured sample.

19.1.3
Overview of SEROA

It seems natural, as it did at the time when SERS was developed, that the surface enhancement phenomenon could also be employed in ROA, and when it succeeds it will allow researchers to overcome the weak signal, high concentration, and longer time acquisition required for ROA. Nevertheless, many attempts were made and no successful result was reported, in spite of the fact that Efrima clearly expressed that "I propose that such measurements (i.e. surface-enhanced Raman optical activity (SEROA)) are feasible," and he predicted that these measurements could contain information on both the target molecule and "local electric fields, their gradients and, in general, local dielectric properties of the metal–air (or metal–solution) interface" (Efrima, 1983). Later, Efrima developed the first theoretical treatment of the metal surface enhancement of ROA bands in a more extensive paper (Efrima, 1985). In 1994, Hecht and Barron developed expressions for ROA scattering, as well as for the case of linearly polarized difference Raman scattering, from chiral molecules on isotropic surfaces, including contributions from antisymmetric contributions of polarizability tensor components for the first time (Hecht and Barron, 1994, 1995). The authors suggested that ROA could be a promising technique for probing the chirality of metal surfaces. Despite these developments, only two instances of SEROA were reported for two decades (Higuchi, 1990; Yu, 1994), but the signal-to-noise level in each case was low and so the results were equivocal. The results, mentioned below, can be considered as the first reported experimental SEROA (Abdali, 2006; Abdali *et al.*, 2007; Johannessen and Abdali, 2007; Abdali and Blanch, 2008).

19.2
Theory of SEROA

Efrima was the first to consider the effects of large electric field gradients on the electric dipole–magnetic dipole and electric dipole–electric quadrupole optical activity contributions to ROA scattering. In his first published report describing this phenomenon, he showed theoretically that additional molecular specific information could be obtained "in a feasible manner" in the vibrational spectra (Efrima, 1983). However, this work only discussed the effect of electric field gradients on ROA, and concluded that the CID (Δ) could be of the order of unity. Efrima also surmised that SEROA spectra should appear very different to the ROA spectra in bulk solution owing to the effects of the plasmon resonance on the contributions to ROA scattering and to the anisotropic environment of the analyte–colloid interface and the local dielectric properties. He also raised the first recommendation for caution in interpreting SEROA spectra. Though this was specifically in terms of the possible responsible mechanism, subsequent studies have indeed shown that the analysis of measured SEROA spectra requires care owing to the experimental artifacts that can arise. Changes in direction of the local field and the simple magnitude of the electric field were shown to be insufficient in themselves to generate large CID values, and that large field gradients are required for this to occur (Efrima, 1985). These field gradients were proposed to be far larger than those associated with the radiation field, which implied that even if the electric field associated with a plasmon resonance was too small in intensity to generate a large SERS signal it may still generate a measurable SEROA signal. Efrima derived the following relationship between CID values for the bulk for nonresonant ROA (Δ_b) and for the surface enhanced, that is SEROA, case (Δ_s) as follows:

$$\frac{\Delta_s}{\Delta_b} \approx \frac{[(E_{\mathrm{loc}}/d)/E_{\mathrm{loc}}]}{[(E_i/2\pi\lambda)/E_i]} \tag{4}$$

where E_i is the incident electric field, E_{loc} is the local contribution to the electric field, d is the range of the local field, and λ is the wavelength of the radiation used.

Reflection from metal surfaces is known to be able to change the polarization state of circularly polarized light to the elliptically polarized state, introducing a linearly polarized component. Therefore, the effect of reflection on the polarization state needs to be taken into account. Efrima concluded that for imperfect metal surfaces, such as metal colloids, a significant degree of CP is still likely to exist in the scattered radiation, and is derived from this work formalisms for CID intensity in both the parallel ($\Delta^{||}$) and perpendicular ($\Delta^{\perp}$) polarizations (Efrima, 1985).

Although most of the scattered radiation is expected to be circularly polarized, it is possible that any linear polarization introduced by reflection may lead to significant artifacts being introduced into measured SEROA spectra. These artifacts would have to be carefully controlled and minimized. Efrima found that the magnetic field component was not expected to make a large contribution to SEROA spectra, which is different to the situation for ROA measurements made in solution, and that near the metal surface only the electric polarizability–electric polarizability contribution was likely to be significant, and a change of the local electric fields direction would not influence the value of the CID. Efrima further suggested that another requirement for the generation of large SEROA signals was either a significant imaginary component to the electric polarizabilities of the analyte on the metal colloid surface or a phase difference between the electric field and its gradient, which is defined as

$$\nabla_\beta E_I = \delta_{\beta,z} \sum_i f_i \hat{i} \tag{5}$$

where $i = x, y, z$ and

$$\begin{aligned} f_x &= [\partial R_x(\theta_i)/\partial z] E^0_{||} \cos\theta_i \\ f_y &= [\partial R_y(\theta_i)/\partial z] E^0_{\perp} \\ f_z &= [\partial R_z(\theta_i)/\partial z] E^0_{||} \sin\theta_i \end{aligned} \tag{6}$$

where the reflection coefficient R depends on the scattering angle and the frequency of the scattered light. As for the CID derivation, Efrima defined the Cartesian component of the electric field emitted in the direction given by the wave vector k and detected at distance r as

$$\begin{aligned} E^\alpha_d = {} & (\omega^2 \mu_0 / 4\pi r) \exp[r/c - t)] \\ & \cdot [1 + R_\alpha(\theta_d)] \cdot \left[\left(\mu_\alpha - \sum_\beta k^\alpha_d k^\beta_d \mu_\beta \right) \right. \\ & - (1/c) \sum_{\beta,\gamma} \varepsilon_{\alpha\beta\gamma} k^\beta_d m_\gamma - (\mathrm{i}\omega/3c) \\ & \left. \times \sum_\beta \left(k^\beta_d \theta_{\alpha\beta} - \sum_\gamma k^\alpha_d k^\beta_d k^\gamma_d \theta_{\alpha\gamma} \right) \right] \end{aligned} \tag{7}$$

where μ and m are the electric- and magnetic-induced dipoles, respectively, and θ is the induced molecular electric quadrupole tensor. These molecular multipoles are defined as (Barron and Buckingham, 1971)

$$\begin{aligned}\mu_\alpha &= \sum_\beta \Big\{\alpha_{\alpha\beta} E_I^\beta + G_{\alpha\beta} B_I^\beta \\ &\qquad + (1/3) \sum_\gamma A_{\alpha,\beta\gamma} (\nabla_\beta E_I^\gamma) + \cdot \Big\} \\ m_\alpha &= \sum_\beta G^*_{\beta\alpha} E_I^\beta + \cdot \\ \theta_{\alpha\beta} &= \sum_\gamma A^*_{\gamma,\alpha\beta} E_I^\gamma + \cdot \end{aligned} \tag{8}$$

where α is the electric dipole–electric dipole polarizability tensor, G the electric dipole–magnetic dipole polarizability tensor, and A is the electric dipole–electric quadrupole polarizability. Evaluation of these CID expressions showed that no matter what the cause of the enhancement will be, whether resonance or chemical effect, there is always a fair chance that ROA could be measured for an adsorbed molecule, and the CID will always be sensitive to the orientation of the adsorbed molecule.

Hecht and Barron (1994, 1995) considered the case of a pure electric dipole surface ROA mechanism, in their attempt to develop the SEROA theory. In these two papers, the authors included antisymmetric polarizability components for the first time, and an incoherent scattering from a chiral molecule attached to an isotropic surface fixed with respect to the laboratory frame was also considered, with averaging of the ROA tensor products over two dimensions, and they showed that CID values much larger than those found for ROA measurements in solution may be possible. That is, the CID expressions for SEROA experiments may be significantly larger than those in conventional ROA experiments. Hecht and Barron found that these CIDs in the vicinity of metal surfaces originate from interference between adsorptive $\alpha_{\alpha\beta}(a)$ and dispersive $\alpha_{\alpha\beta}(d)$ electric dipole–electric dipole molecular polarizability tensor components:

$$\tilde{\alpha}_{\alpha\beta} = \alpha_{\alpha\beta}(d) + \mathrm{i}\alpha_{\alpha\beta}(a) \tag{9}$$

where $\tilde{\alpha}_{\alpha\beta}$ characterizes Cartesian components of the complex electric dipole–electric dipole polarizability tensor, and both the adsorptive and dispersive parts of the polarizability are purely real in the absence of a time-odd influence such as a static external magnetic field.

This situation will only be observed under resonant, or preresonant, conditions. It was pointed out by Hecht and Barron that isotropic surface ROA would vanish for achiral molecules and would give signals of equal magnitude, but opposite sign for two enantiomers, thereby leading to zero ROA. If a plane containing the normal to the metal surface and one of the axes parallel to the surface is considered, then a reflection across this plane changes the sign of off-diagonal components in the polarizability tensor. This reflection generates an enantiomeric isotropic surface for chiral molecules, but an identical surface for achiral molecules. Hecht and Barron also noted that although some achiral point groups may exhibit chiral projections on a surface, these examples would not be expected to give ROA from isotropic surfaces owing to the cancellation of enantiomeric projections, though surface ROA could still arise from an ordered surface.

A full orientational averaging and dressed molecular response tensors for scattered circular polarization (SCP) ROA was recently reported, though this formulasim is equally applicable to all ROA experimental configurations (Janesko and Scuseria, 2006). These researchers considered the fields produced by the multipoles that were induced in a molecule by an oscillating light wave, and the response they would generate in the metal substrate in order to specify the multipole moments of the molecule–substrate system. Janesko and Scuseria derived expansion coefficients for these multipole moments and thus determined general selection rules and scaling laws for SEROA experiments. For the simple model system of a dipolar sphere, they found that predicted SERS intensities agreed well with measured SERS intensities and that SERS enhancements for vibrational modes, whose polarizability derivatives are parallel to the surface normal, are 16 times larger than for those modes whose polarizability derivatives are parallel to the surface. Janesko and Scuseria also found that SEROA intensity scales with respect to an order parameter and that there were no SEROA contributions lower than first order of this parameter when full orientational averaging was taken into account. This finding is in contrast to the earlier model proposed by Efrima (1985) and leads to CID values smaller than those for ROA of bulk samples.

Janesko and Scuseria then considered quadrupolar spheres as substrates, and found that the CID values for these substrates could be much greater due to the existence of a gradient enhancement mechanism across the metal substrate particle rather than just across the molecule. They determined that the maximum CID using this model was of the order of 10^{-2}, and CID values could possibly be even higher for more realistic substrates. Dressed ROA tensors derived by Janesko and Scuseria contained contributions from the molecular polarizability, which gives rise to SEROA scattering that scales purely as the mean polarizability. This finding is similar to the chiral surface effect considered by Hecht and Barron (1994, 1995), and was again predicted to be nonzero only for chiral molecules. Janesko and Scuseria also predicted differences between incident circular polarization (ICP) and SCP ROA spectra, which are similar to the case of ROA measured under resonance or near-resonance conditions with an excited electronic state of the molecule, and this may be owing to differences in the molecular response to the incident and scattered fields. The introduction of quadrupolar responses to the model further suggested that CIDs could also be enhanced for dipolar nanorods used as substrates.

This multipole EM field expansion model was recently reworked by Bour into a matrix formalism (Bour, 2007). Using this new approach, Bour computed SEROA spectra of CHFClBr considering a single colloidal sphere and for the situations of an analyte between two colloidal spheres or between four chirally arranged colloidal spheres. Large differences were found between computed SEROA bands, both in sign and intensity, for these three situations, showing that SEROA spectral profiles should be highly sensitive to changes in both analyte–colloid and colloid–colloid interactions, than the corresponding SERS spectra. Bour also found that increasing the number of colloidal spheres around an analyte molecule increased

CID values, and confirmed the importance of quadrupolar contributions.

Recent work has also been published, modelling polarization effects in SERS, which is particularly relevant to SEROA (Etchegoin, Galloway and Le Ru, 2006). These authors reported that the local electric field of the plasmon resonance has a significant effect on the polarization state of both the incident and scattered waves. Such effects would need to be carefully considered both for the design of SEROA experiments and for the interpretation of measured SEROA spectra. The effect of relative orientation of a dimer hot spot with respect to the angle of incidence of the light wave suggested that large CID enhancement factors for SEROA measurements were not likely in typical situations. Etchegoin *et al.* further cautioned that measurement of SEROA may require differentiation between small signals originating from the analyte and large background, or artifactual, signals.

19.3
ROA Instrumentation

An ROA spectrometer has only recently become commercially available, as mentioned above, and it is mainly based on novel work by Hug and Hangartner (1999). The use of CP of light is fundamental to any ROA instrument, and different combinations exist depending on whether the CP takes place before the sample, that is, in the incident path (ICP), or after scattering from the sample, that is, in the scattered path (SCP), or their combination in the form of dual circular polarization (DCP), that is, in both the incident and scattered directions. An excellent discussion of these different forms of ROA has been presented by (Nafie and Che, 1994). The different mechanisms are schematically shown in Figure 19.1. It is worth mentioning that the existing commercial ROA instrument, Chiral*RAMAN*, employs the SCP mechanism, although half waveplates are also mounted, both in the incident and scattering path to average out any linear birefringence in the beam. This eliminates the so-called flicker noise, which usually exists (and influences the results) due to dust particles, density fluctuations, laser power fluctuations, and so on. This is important because the intensity difference measurements required to extract the circularly polarized components of the scattered beam are taken between two orthogonal components of the scattered light measured during the same acquisition period. Employing such a technique, that is, cancellation of the "flicker noise," has greatly improved signal-to-noise characteristics, by approximately a factor of 5 compared to the ICP ROA design previously used, allowing ROA spectra to be measured for lower sample concentrations and in far shorter timescales. Today, the Chiral*RAMAN* instruments in use utilize excitation wavelength of 532 nm and the ROA spectra recorded are virtually identical to ROA spectra measured using ICP instruments. Recently, a new Chiral*RAMAN* SCP ROA spectrometer has been reported, and this spectrometer utilizes near-infrared excitation at 780 nm (Nafie *et al.*, 2007). Such an excitation is intentionally chosen so that it will minimize the presence of fluorescence, and because of the properties of metals, it will allow investigation of the SEROA phenomenon using gold substrates rather than the silver colloids investigated so far. DCP ROA

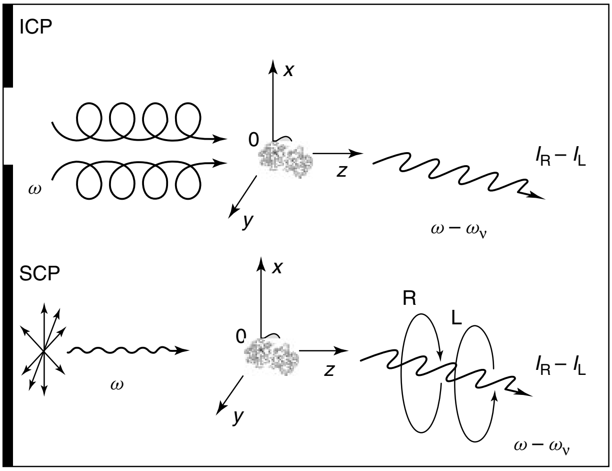

Fig. 19.1 Different mechanisms of ROA are schematically shown. The incident circular polarization (ICP) makes use of the circular polarization of the incident light (top), whereas scattered circular polarization (SCP) makes use of the circular polarization of the scattered light (bottom). I_R and I_L refer the intensity of the beam for the right and left circular polarized light, respectively.

spectroscopy has been less widely exploited and it relies upon either in-phase (DCP_I) or out-of-phase (DCP_{II}) measurement of scattering using both incident and SCP. All the results presented here were obtained using Chiral*RAMAN* instruments at 532 nm.

19.4
SEROA, Measurement Results

19.4.1
SEROA of Small Molecules

As the theoretical work discussed above has indicated, care must be exercised in the analysis of measured SEROA spectra. Figure 19.2 presents relevant SERS and SEROA spectra measured for proline. The top two panels show the conventional Raman and ROA spectra collected for a solution of proline (0.939 M), with 700 mW of laser excitation and 81 minutes of data collection. In the third panel are shown the SERS spectra measured for 8.8 mM proline in the presence of citrate- and hydroxylamine-reduced silver colloids, and with 20 mM K_2SO_4 used as an aggregating agent for both sols. The corresponding SEROA spectra for proline in these two silver sols are shown in the fourth panel with 100 mW laser excitation at 532 nm and 60 minutes of data acquisition. These spectra are unprocessed and show that there are a number of bands common to both measurements, in the range ~1300–1550 cm^{-1}, which indicates possible SEROA bands originating from the proline analyte. The CID values of these SEROA features appear to be of the order 10^{-3} to 10^{-4}, which is similar to CID values measured for the conventional ROA spectra of proline. There are clearly significant differences between the features displayed in the

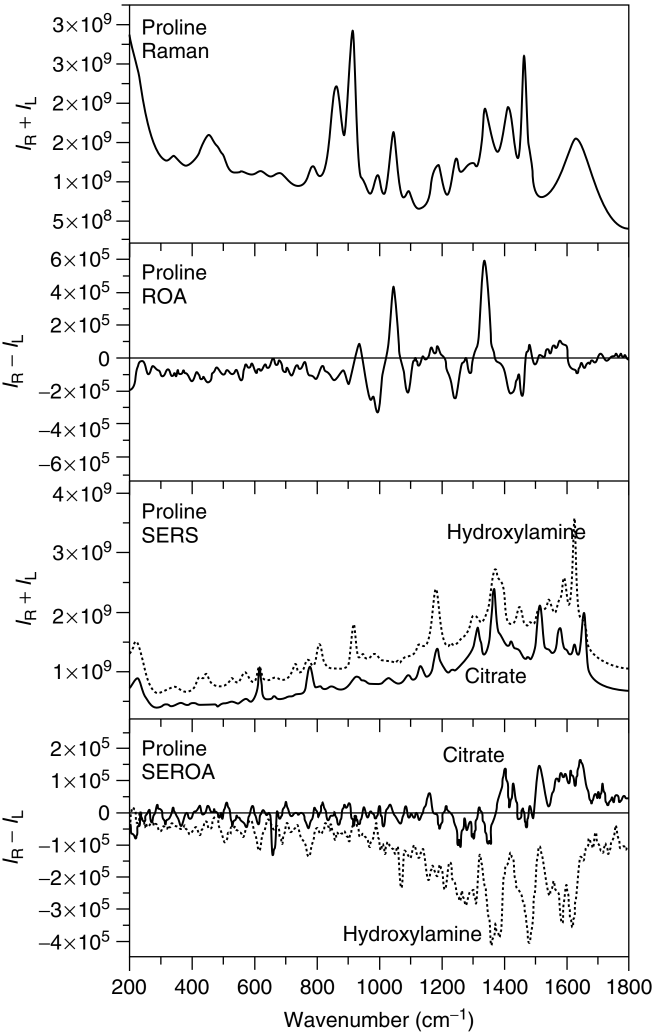

Fig. 19.2 SERS and SEROA spectra measured for proline. The top two panels show the conventional Raman and ROA spectra collected for a solution of proline (0.939 M) at 700 mW laser excitation and 80 minutes of data acquisition. The third panel shows the SERS spectra collected for a solution of proline (8.8 mM) in two Ag colloids; citrate and hydroxylamine. The corresponding SEROA spectra are shown in the fourth panel, at 100 mW laser excitation and 60 minutes of data acquisition.

ROA and SEROA spectra, as Efrima suggested would be observed (Efrima, 1985). There are also differences between the two SEROA spectra shown, with the SEROA spectrum measured for the hydroxylamine-reduced colloids being distorted in a negative direction compared to the SEROA spectrum measured for citrate-reduced colloids. Thus, several SEROA features have been distorted, particularly the two negatively signed bands found near 1600 cm^{-1}. Similar distortions are sometimes observed in conventional ROA spectra from polarized Raman bands. These polarization effects induced by plasmon resonances may be significant and so should be considered when evaluating SEROA spectra (Etchegoin, Galloway and Le Ru, 2006).

The distortion effects of these polarizable SERS bands on the features of SEROA spectra are also observed for the nucleoside cytidine in Figure 19.3. SERS spectra for cytidine (at 5.8 μM concentration, 75 mW laser excitation, 3.5 minutes data acquisition per spectrum, using citrate-reduced silver colloids and 3.8 mM NaCl as aggregating agent) are shown in this figure at time intervals of 20 minutes throughout the aggregation process. We can see that the SERS spectral profile is consistent for each of these spectra with the absolute intensity of each band changing in the same proportion to all others shown. In contrast to this, greater changes are apparent in the corresponding SEROA spectra, as shown in the lower panel in Figure 19.3. Several bands in this panel, originating from intense SERS bands, appear to decrease in relative intensity, indicating that these bands are not real SEROA bands but are probably artifacts and are being averaged out over time. After approximately 45 minutes several weak bands begin to appear; such as those at ∼400, 1270,

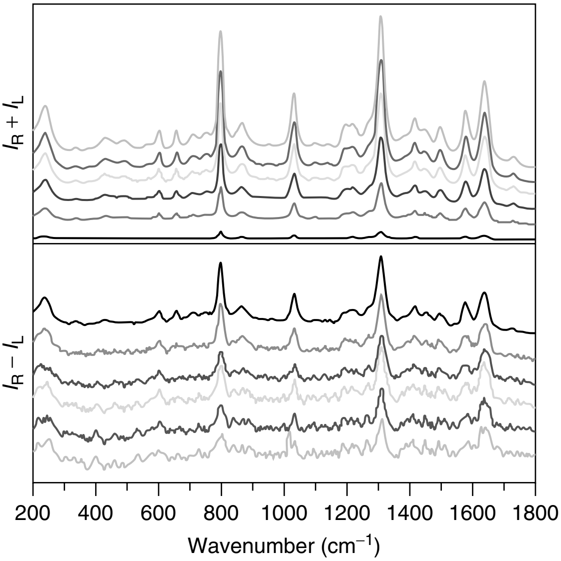

Fig. 19.3 SERS (top) and SEROA (bottom) spectra measured for cytidine with the following time interval of 20 minutes, starting with black (after 5 minutes) and ending with green (after 105 minutes). SERS intensities increase with time, whereas SEROA features associated with large SERS bands, and therefore prone to artifacts, become less intense, revealing weaker features in the SEROA spectra. (Please find a color version of this figure on the color plates.)

and 1460 cm^{-1}; suggesting that these weak features are real SEROA bands originating from the cytidine analyte. Although the SEROA spectra presented in Figures 19.2 and 19.3 are not yet definitive proof of the SEROA technique, they do show the importance of careful characterization of SEROA bands and how these can vary with respect to time and the aggregation behavior of the colloids in the sol.

19.4.2.
SEROA of Protein

A SEROA measurement of a chiral pentapeptide, enkephalin, was reported at the ICORS conference in 2004, and the results were later published (Abdali, 2006). This work illustrates the possibility of detecting SEROA, and the same group succeeded to employ SEROA in a series of recent publications. In these reports, it has been shown that recording a SEROA spectrum does not take place whenever a SERS spectrum is recorded, as it is the case for ROA and RS. Here, great care should be taken for optimizing the system, and SEROA is conditioned by optimization of the concentration of the analyte, colloid, and aggregating agent composing the sample (Abdali *et al.*, 2007). In Figure 19.4, the intensities of two resonance SERS peaks for myoglobin at 532 nm are plotted as a function of the concentration of myoglobin, Ag colloids, and NaCl, respectively. The two peaks, representing the symmetric (1374 cm^{-1}) and antisymmetric (1169 cm^{-1}) ν (pyr half ring) stretching modes were chosen to monitor SERS intensity owing to the fact that these peaks were found to be independent of the signal-to-noise ratio.

The concentration conditions are clearly seen to influence the results, in that any variation of the concentration of one of the sample components yields variation in the corresponding SERS. Accordingly, a series of different concentrations was investigated, from which the optimum conditions were found to be 10^{-7} M myoglobin, 70% Ag, and 0.1 M NaCl, in order to achieve the best SERS measurement of myoglobin, as shown in Figure 19.4.

It is known that the number of molecules per unit volume is important in any Raman measurement, whereas the number of molecules currently adsorbed at the SERS active sites influences the measured SERS intensity. This explains the behavior of the intensity observed in Figure 19.4, in which as the sample concentration initially increases the number of SERS active sites will also increase, and consequently higher SERS intensity will be obtained, a tendency that continues until a maximum value of the intensity is reached. Beyond this point, any increase in the sample concentration will yield a decrease in SERS intensity due to an increase in the background or/and increased fluorescence, which results from the aggregation of sol, leading to an increase in opacity, especially in the case of colored samples, such as myoglobin.

Resonance enhancement of Raman scattering (Resonance Raman Spectroscopy) occurs when an electronic transition is triggered by the incident light. The electronic excitation increases the Raman scattering probability of vibrational normal modes in the spatial vicinity of the chromophore, thereby enhancing these signals due to the scattering cross section enhancement by usually up to five orders of magnitude.

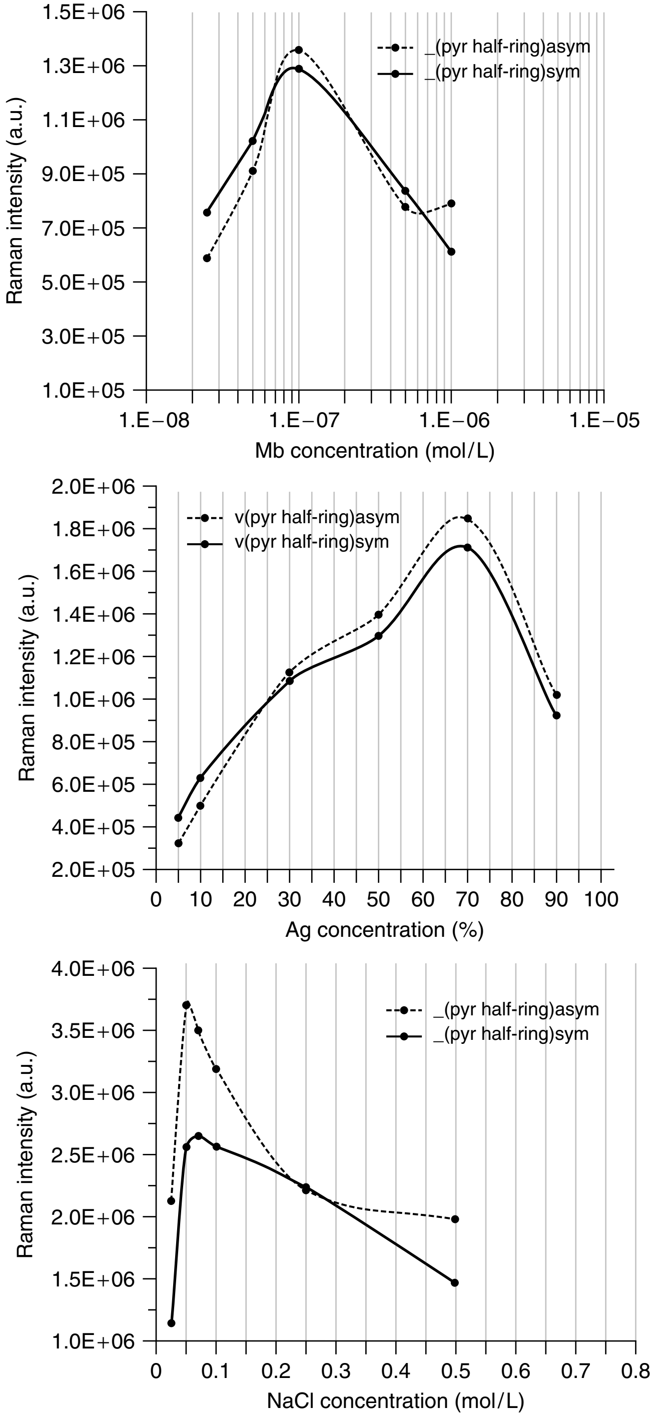

Fig. 19.4 The optimization of the Mb concentration (top), the colloids Ag (middle), and the aggregating agent NaCl (bottom).

When RRS enhancement couples with surface plasmon enhancement, a further enhancement of the resonant vibrations occurs, known as *surface-enhanced resonance Raman scattering (SERRS)*. Therefore, the SERS measurement of myoglobin using 532 nm excitation shown in Figure 19.4 is in fact a SERRS spectrum. Of course, SERRS measurements are only possible when there is sufficient overlap between the electronic transition frequency of the sample and the surface plasmon resonance of the nanoparticles. It is also known that measurement of ROA under electronic resonance conditions leads to resonance Raman optical activity (RROA), and the combination of electronic resonance with SEROA generates resonance surface-enhanced Raman optical activity (SERROA).

The RROA and SERROA spectra of myoglobin, using 532 nm line source, are also shown in Figure 19.5, with the SERROA measurement being carried out under the optimized conditions, as shown in Figure 19.4. Although chiral peaks in the spectrum were observed after only a few minutes, in order to achieve a better signal-to-noise ratio, the measurement was performed for 5 minutes. The SERRS signal was simultaneously monitored for erratic hot spots, and found to be stable during the experiment. In order to verify the authenticity of the surface-enhanced effect, an RROA spectrum of myoglobin of 100 μM concentration was also recorded, as shown in Figure 19.5, and was obtained during no less than 32 hours. This time was necessary to achieve a sufficient signal-to-noise ratio. Comparing the RROA and SERROA spectra in Figure 19.5, it is noticeable that the chiral signals of myoglobin, labeled with corresponding frequencies, are similar in both the spectra. In particular, the region 1300–1400 cm^{-1}, which also exhibits the largest signal enhancement in the SERRS spectrum, has a considerable signature overlap around 1395, 1353, 1321, and 1299 cm^{-1}. However, the SERROA peak around 1353 cm^{-1} appears to have bigger line width (full width at half maximum (FWHM)) than the corresponding RROA feature as shown in Figure 19.5, which may explain the absence of bands at ~1366 and 1344 cm^{-1}. The Raman bands in this region have previously been assigned to vibrations of the heme group in the protein, and

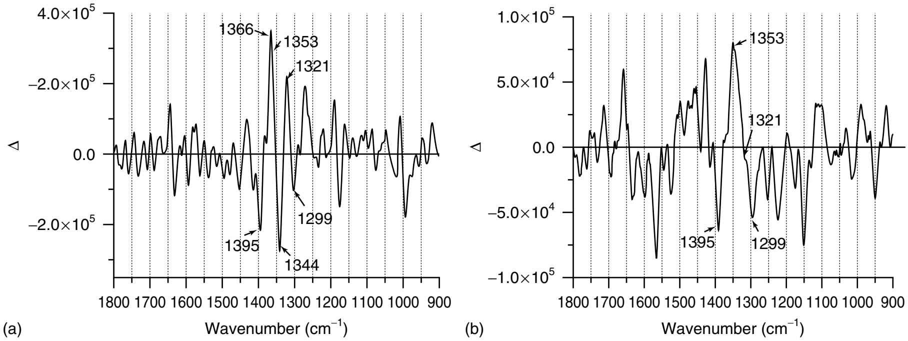

Fig. 19.5 Myoglobin spectra using (a) RROA for 100 μM and 32 hours acquisition and (b) SERROA for 100 nM and 30 minutes acquisition. The SERROA measurement carried out under the optimized conditions is shown in Figure 19.4.

have been shown to be enhanced by the resonance Raman effect, using an excitation source of 532 nm (Bizzari and Cannistrato, 2002). At 100 μM concentration of the sample, conventional ROA bands from polypeptide backbone vibrations would be too weak to measure, so the peaks found in the RROA spectrum in Figure 19.5 were assigned to the resonance enhancement of the porphyrin vibrations.

Employing the same optimization conditions, SERRS and SERROA spectra of another porphyrin-containing protein, cytochrome *c*, were also reported (Johannessen and Abdali, 2007). However, in this work hydroxylamine-reduced silver colloids were used (Leopold and Lindle, 2003). The RRS, RROA, SERRS, and SERROA spectra of cytochrome *c* are shown in Figure 19.6. It is worth mentioning that RROA features observed for cytochrome *c* are not similar to those usually observed for globular proteins. This clearly illustrates that the measured chiral signals originate due to vibrations of the porphyrin ring. In the range 1100–1700 cm^{-1}, most of the RRS bands observed for cytochrome *c* are assigned to strongly enhanced in-plane vibrations that also give rise to contributions for the major features in the RROA spectrum shown. Although the ν_{10} and ν_{11} transitions have positive RROA, the ν_{19} signal, located between these vibrations, appears to be a negative–positive couplet, indicating contributions from two transitions. Furthermore, it is clear that the observed signals originate from the porphyrin group in a chiral environment.

The bands ν_{20} and ν_4, both of which exhibit positive ROA, are due to the in-plane transition. In this region of the spectrum, the predominant feature is due to the ν_4 transition, whose resonance enhancement is highly sensitive to

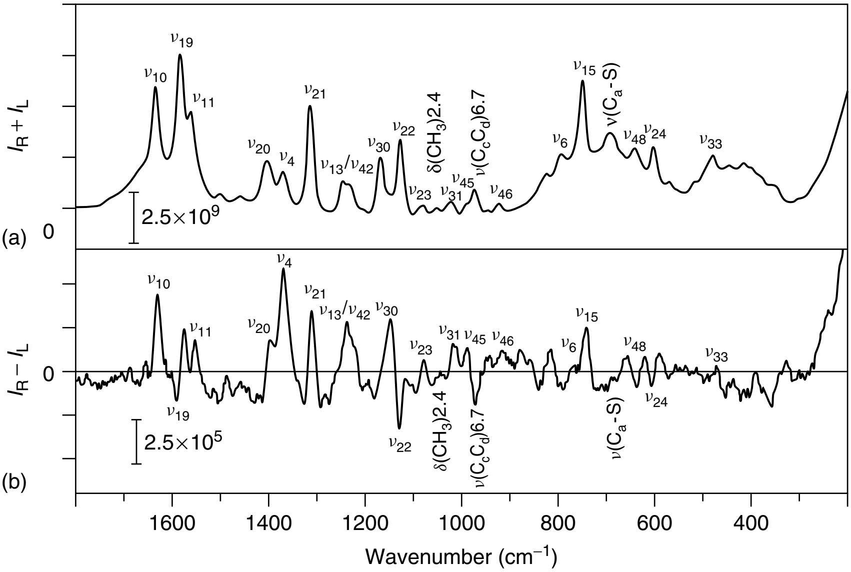

Fig. 19.6 Vibrational (a) RRS and (b) RROA spectra of cytochrome *c* with concentration of 100 μM and 16 hours acquisition time.

the excitation wavelength; however, it does not seem to be very strongly enhanced by the Q-band excitation caused by the 532 nm laser used for this measurement. This is apparently because the collective half ring stretching vibration, responsible for the ν_4 signal, is highly chiral and results in a strong signal.

Local in-plane deformations and side chain vibrations having weak ROA contributions can be assigned to the region between 800 and 1100 cm^{-1}, where less enhanced SEROA signals can be seen. Nevertheless, the two overlapping bands assigned to ν_{45} and the propionate stretching vibration at $\sim$974 cm^{-1} appear as a positive–negative couplet in the RROA spectrum. In the region below 800 cm^{-1}, ν_{15} is strongly enhanced and represents the main feature in this region, and it yields a positive RROA signal, whereas limited or no ROA signals can be found in this region.

It is noticeable that to a certain degree the enhancements of Raman active transitions in SERRS correlate with the corresponding SERROA signals. In the wavenumber region ($>$1100 cm^{-1}), the signals corresponding to the ν_{10} and ν_{11} transitions are observed as positive peaks in the RROA spectrum, whereas the signal of ν_{19} couplet appears to be within the noise level. This shows that although the first two transitions, ν_{10} and ν_{11}, are enhanced, the plasmon effect is not the same on the later transition ν_{19}. The absence of SERROA here may also be a consequence of an increased polarization of the transition (or transitions), which yields artifact prone data collection. Such comparisons can also show the considerable enhancement of ν_{20} SERROA signal due to the plasmon effect than that seen in the RROA spectrum. On the other hand, the adjacent ν_4 transition seems to undergo no further enhancement in the SERROA spectrum. It is therefore of importance to conclude that the RRS spectrum of cytochrome *c* shows a remarkable enhancement of the ν_4 transition compared to ν_{20}, whereas this is absent in the SERROA spectrum, an effect that is apparently the opposite for the ν_{20} transition.

Other significant differences between RROA and SERROA spectra of cytochrome *c* are also clearly observed in number of bands. The ν_{30} band in the SERROA spectrum is very weak compared to that in the RROA spectrum. This may be due to the changes of the dipole moment and polarization of the molecule, upon adsorption to the silver colloids, or as a result of the symmetry changes in the porphyrin ring. Such inversions taking place in the prosthetic group can explain the total inversion of the ν_{22} band in the SERROA spectrum. Another inversion can also be seen in the couplet around 1000 cm^{-1}, which is assigned to overlap the ν_{45} and the propionate stretching vibration at 974 cm^{-1} in the RROA spectrum. While this couplet appears as a positive-negative feature in the RROA spectrum, the SERROA spectrum reveals a weak negative-positive couplet, the negative portion of the couplet commencing immediately after ν_{31}. In addition to being an interesting contribution to the general understanding of the plasmon effect and the influence on adsorbed molecules to metal surfaces, such behaviors of these bands also necessitates more caution, when assignments are to be made using a comparison between ROA SERROA spectra. In this regard, Janesko and Scuseria (2006) found that quadrupolar responses of the substrate may significantly enhance ROA in certain cases, which could explain the apparent lack of SERRS signal from, for example, ν_{21} as the SERROA signal is enhanced.

Like ROA spectra, SEROA spectra have also been shown to have sensitivity to ligand binding (Johannessen, White and Abdali 2007). In this work, the authors extended the SERROA study of myoglobin discussed in Figure 19.5 to investigate the sensitivity of SEROA spectra to small changes in the molecule, specifically the effect of adding a ligand (azide) to myoglobin. The results showed that the SERRS spectrum of the myoglobin–azide complex was almost identical to the SERRS spectrum of myoglobin, as shown in Figure 19.4, whereas larger differences were observed between their corresponding SERROA spectra. This result shows that the sensitivity to perturbations of the molecule structure inherent to ROA spectroscopy can be retained in SERROA.

It is clear from Figure 19.7 that although spectral changes occur in the RRS spectra of myoglobin, above 1500 cm^{-1}, upon complexation of the azide ligand, only few changes are found between the SERROA bands. This implies that the localized porphyrin transitions, which are found in this region, are less susceptible to chiral analysis. However, it should be emphasized that the structural changes induced by complexation of azide, or other small ligands, in metalloproteins that contain porphyrin are very small, that is, <0.5 Å. Such changes cannot be determined directly even by X-ray diffraction. Therefore, the

ability of SERROA to detect these structural changes is highly promising for future work of this nature.

19.5
Future Perspectives

The gold rush after methods and tools to detect single molecules has been ongoing since a long time, and there has certainly been great progress in this field. Raman variant techniques, that is, Raman spectroscopy, ROA, SERS, SEROA, have potentially important roles in biology due to the capability of these tools to operate *in vivo, in vitro*, and *in silico*, and without damaging the studied molecule. Today, these tools are applied in biology, chemistry, medicine, drugs industry, art and archaeology, forensic chemistry, and many other fields. Further developments in Raman and Raman-combined methods are expected to continue, particularly in instrumentation, which are expected to widely spread the applications of vibrational spectroscopy, and this can already be seen in combining Raman to many spectroscopic methods such as fluorescence, optical tweezers, atomic force microscopy (AFM), and the new tool, designated *tip-enhanced Raman scattering* (*TERS*) (Domke, Zhang and Pettinger, 2006). TERS seems to have wide potential, for instance, when combined with surface-enhanced method, for example tip enhanced Raman optical activity (TEROA); the effect will be studied in a more controlled manner. Theoretical models of SEROA are also expected to quickly develop in the next few years as polarized spectroscopies are becoming a more popular field of research and the sophistication of computational methods is now sufficient to calculate these spectra. Such models will continue to be informative about the mechanisms responsible for SEROA and they will provide a basis for interpretation of measured SEROA spectra, which can otherwise be difficult. A more detailed understanding of the theory of Raman techniques coupled with more advanced instrumentation, such as optical tweezers and stretchers, patch clamps, and so on, will undoubtedly take Raman single molecule detection to a much more sensitive level, and we may expect to see these tools being utilized in the near future for diagnostic analysis and control in different biomolecular fields.

20.1
Introduction

The first detection of the fluorescence light of a single molecule dates back to 1976 (Hirschfeld, 1976). At that time, the molecule under investigation bore about 100 fluorescent chromophores. With the advent of extremely sensitive photon detectors and effective filters, the detection of the fluorescence of just a single fluorophore became possible in 1990 (Orrit and Bernard, 1990), however, in a crystalline host at liquid helium temperature. In the same year, single fluorophores were observed in solution at room temperature (Shera *et al.*, 1990), paving the way to the application of single-molecule fluorescence on biological systems in their native surrounding. The next milestones for the perception of single-molecule fluorescence as a useful biophysical technique were the demonstration of fluorescent resonance energy transfer on an individual basis (Ha *et al.*, 1996) and the direct observation of the diffusion of a dye-labeled protein in a lipid bilayer (Schmidt *et al.*, 1995). These two key experiments sparked a tremendous development of the technique over the following years, and already in 2001 the coming-of-age of single-molecule spectrosocopy was stated (Kelley, Michalet and Weiss, 2001). Today, the number of groups performing single-molecule fluorescence detection as well as the number of publications in the field is rapidly growing. The pioneers of single-molecule fluorescence have set out their children, and their grand children are starting their own groups. This chapter, therefore, cannot be comprehensive, but rather a selection of prototype experiments demonstrating the enormous potential of single- molecule fluorescence for molecular protein biophysics, with an emphasis on protein conformation in the context of protein folding and catalysis. Owing to space limitations, the fields of single-molecule observations of molecular motors and of membrane diffusion will be omitted.

Therefore, the aspects of the respective applications will be balanced by the methodological developments. The very aim of this approach is to provide the reader with a framework of knowledge that helps decide whether a single-molecule approach to a certain problem might be advantageous, and which method is to be preferred.

The basic photophysical principles underlying fluorescence detection, particularly at the high excitation rates necessary to observe the faint light of a single dye molecule, will be outlined in Section 20.2. Section 20.3 will briefly introduce the experimental layouts used, emphasizing their advantages and drawbacks. Having put those ingredients together, Section 20.4 can concentrate on selected applications.

20.2
Photophysical Basics

20.2.1
Energy Levels and Transitions

The fluorescence of single dye molecules is based on the same energy level scheme as ordinary molecular bulk fluorescence, consisting of, in the simplest case, an electronic ground state, an excited state, and a triplet state. In each electronic level, several vibronic states exist. The high repitition rates needed to obtain a measurable signal, however, demand a second look at the energy levels and transitions involved. Besides the levels found in every textbook, higher excited states are shown in the Jablonski diagram in Figure 20.1. Those higher levels exist in the singlet as well as in the triplet manifold. At high laser intensities, in particular in pulsed excitation, further excitations from the states S_1 and T_1 are possible.

Taking first only transitions between the electronic ground state S_0, the first excited singlet state S_1, and the first excited triplet state T_1 into account and neglecting stimulated emission, the following set of rate equations can be derived:

$$\begin{aligned}\dot{n}_1 &= -I\sigma n_1 + k_{\mathrm{rad}} n_2 + k_{\mathrm{ic}} n_2 + k_{\mathrm{risc}} n_3\\ \dot{n}_2 &= I\sigma n_1 - k_{\mathrm{rad}} n_2 - k_{\mathrm{ic}} n_2 - k_{\mathrm{isc}} n_2\\ \dot{n}_3 &= k_{\mathrm{isc}} n_2 - k_{\mathrm{risc}} n_3\end{aligned} \tag{1}$$

Here, n_1, n_2, and n_3 are the occupation probabilities of S_0, S_1, and T_1, respectively, k_{rad} the radiative rate, k_{ic} the rate of internal conversion, k_{isc} the intersystem crossing rate, k_{risc} the reverse intersystem crossing rate, I the excitation intensity, and σ the absorption cross section of the fluorophore.

The quantum yield of fluorescence Φ_f is the ratio of radiative transitions from

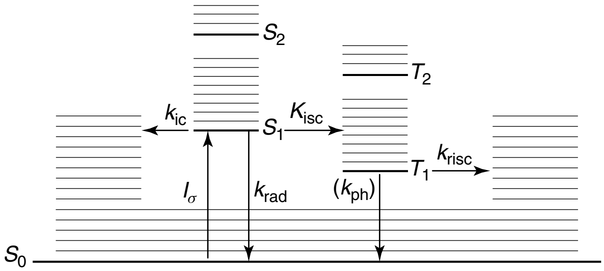

Fig. 20.1 Jablonski diagram showing the electronic ground state S_0, the first and second electronically excited singlet states S_1 and S_2, the first and the second electronically excited triplet states T_1 and T_2, and the most important transitions between the states as detailed in the text.

S_0 to all other transitions from that state:

$$\Phi_f = \frac{k_{\text{rad}}}{k_{\text{ic}} + k_{\text{isc}} + k_{\text{rad}}} = k_{\text{rad}}\tau_f \qquad (2)$$

Here, τ_f is the fluorescence lifetime, which is the experimentally accessible time constant of the decay of fluorescence after pulsed excitation. Therefore, the quantum yield of fluorescence can be determined by measuring the fluorescence lifetime and deriving k_{rad} from the absorption and emission spectra of the dye, making use of the relation between the Einstein coefficients for absorption and spontaneous emission (Strickler and Berg, 1962):

$$k_{\text{rad}} = 2.88 \times 10^{-9} n^2 \frac{\int F(\bar{\nu}) d\bar{\nu}}{\int F(\bar{\nu}) d\bar{\nu}/\bar{\nu}^3} \times \int \frac{\varepsilon(\bar{\nu})}{\bar{\nu}} d\bar{\nu} \qquad (3)$$

Here $F(\bar{\nu})$ is the fluorescence and $\varepsilon(\bar{\nu})$ the absorption spectrum of the dye, with $\bar{\nu}$ the wave number in cm^{-1}. Fluorophores for single-molecule spectroscopy should have quantum yields of fluorescence close to unity to ensure a strong enough fluorescence signal to be detected. Therefore, the intersystem crossing rate as well as the rate of internal conversion should be small.

Under stationary conditions (all time derivatives are zero), the emission rate R as a function of the excitation rate from the set of rate equations (1) is given by

$$R = n_2 k_{\text{rad}} = \frac{k_{\text{rad}}}{1 + \frac{k_{\text{isc}}}{k_{\text{risc}}} + \frac{k_{\text{rad}} + k_{\text{ic}} + k_{\text{ies}}}{I\sigma}} \qquad (4)$$

Owing to increasing population of the triplet state T_1 at high excitation rates, the maximum achievable emission rate with infinitely strong excitation is R_∞:

$$R_\infty = \frac{k_{\text{rad}}}{1 + \frac{k_{\text{isc}}}{k_{\text{risc}}}} \qquad (5)$$

The emission rate R can be rewritten as

$$R = R_\infty \frac{1}{\left(1 + \frac{I_{\text{sat}}}{I}\right)} \qquad (6)$$

with the saturation intensity I_{sat}, which is the excitation intensity where half of the maximum emission rate is reached, given by

$$I_{\text{sat}} = \frac{k_{\text{risc}}}{\sigma} \frac{k_{\text{rad}} + k_{\text{ic}} + k_{\text{isc}}}{k_{\text{risc}} + k_{\text{isc}}} \qquad (7)$$

The saturation of the average emission rate due to triplet excursions is known as the *triplet bottleneck*.

The solution of the set of rate equations (1) with the initial condition of $n_1 = 1$, $n_2 = n_3 = 0$ provides the time evolution of the occupation probability of the first electronically excited singlet state $n_2(t)$, which is related to the fluorescence intensity autocorrelation function or second-order autocorrelation function $g^{(2)}(t)$ defined as

$$g^{(2)}(t) = \frac{< n(\tau) n(t+\tau) >_\tau}{< n(\tau) >_\tau^2} = \frac{n_2(t)}{< n_2 >} \qquad (8)$$

and which reads

$$g^{(2)}(t) = 1 - \frac{k_{\text{isc}}^{\text{eff}} + k_{\text{risc}}}{k_{\text{risc}}} e^{-(k_{\text{rad}}+2I\sigma)t} + \frac{k_{\text{isc}}^{\text{eff}}}{k_{\text{risc}}} e^{-(k_{\text{isc}}^{\text{eff}}+k_{\text{risc}})t} \quad (9)$$

where the effective intersystem crossing rate $k_{\text{isc}}^{\text{eff}}$ is given by

$$k_{\text{isc}}^{\text{eff}} = < n_2 > k_{\text{isc}} \quad (10)$$

The theoretical autocorrelation function of a single dye molecule according to Eq. (9) is shown in Figure 20.2 on a logarithmic timescale. This function drops to zero at the temporal origin, which is intuitively understood taking into consideration that a single quantum system can never emit two photons simultaneously. This behavior is referred to as *photon antibunching*. Thereafter, the autocorrelation function takes a value above one, indicating that the occupation probability of S_1 at this time is higher than on average. This can be understood since the system will always be excited first to S_1, but on average the occupancy $< n_2 >$ is limited by the triplet bottleneck. Because of triplet excursions, a single molecule emits its photons in bunches (cycling in the singlet manifold under photon emission), separated by dark periods (when the molecule is shelved in the triplet state). Therefore, the second term in Eq. (9) is referred to as the *photon bunching* term. If dynamical processes are to be studied by single-molecule fluorescence, care has to be taken that photophysical effects do not lead to misinterpretations.

20.2.2
Energy Transfer

Energy transfer between two or more fluorescent entities is a major subject in single-molecule fluorescence. It plays an important role in light harvesting complexes, and, on the other hand, is the basis of one of the most popular single-molecule techniques, fluorescence resonance energy transfer (FRET), which is

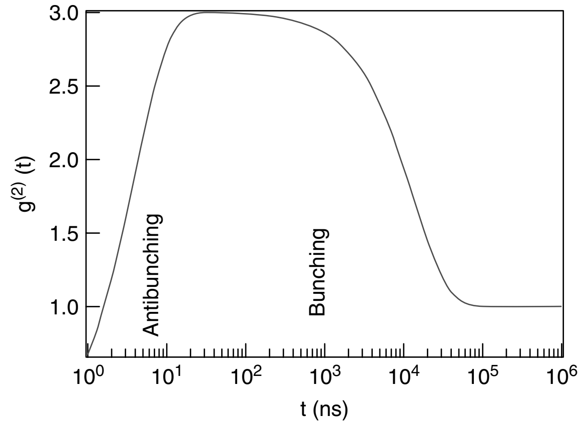

Fig. 20.2 Intensity autocorrelation function of the fluorescence of a single dye molecule under room temperature excitation.

referred to as a *molecular ruler* (Stryer and Haugland, 1967) because of its capability to measure distances between two fluorophores by spectral means.

In FRET, one fluorophore, called *donor*, is excited, and the exitation energy is transferred in a radiationless manner to a nearby fluorophore called *acceptor*. The two chromophores may be chemically identical (homotransfer) or distinct (heterotransfer). The transfer mechanism is based on the dipole–dipole interaction between the two fluorophores in the weak coupling regime, that is, the interaction energy is small compared to the transition energies. The transfer efficiency theoretically derived by Förster (1946) depends on the relative location and orientation of the transition dipoles of the fluorophores, their distance R, the refractive index of the medium n in the vicinity of both, and the overlap integral J. The latter is taken into account for the resonance condition and is the integral of the product of the normalized emission spectrum of the donor $F_D(\lambda)$ and the absorption spectrum (molar extinction coefficient in $\text{cm}^{-1}\text{M}^{-1}$) $\varepsilon_A(\lambda)$ of the acceptor:

$$J = \int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 d\lambda \tag{11}$$

The transfer rate, that is, the rate with which the excited donor transfers its energy to the acceptor, is given by

$$\begin{aligned} k_t &= 8.8 \times 10^{-23}\text{mol}\frac{1}{\tau_D}\frac{1}{R^6}\frac{\kappa^2\Phi_D}{n^4}J \\ &= \frac{1}{\tau_D}\left(\frac{R_0}{R}\right)^6 \end{aligned} \tag{12}$$

with the distance R taken in Angstrom and R_0 the Förster radius. Here, the relative position and orientation of the dyes is taken into account through the orientation factor κ^2. Values of κ^2 for some cases are shown in Figure 20.3. The orientation dependence of the energy transfer rate may jeoperdize distance measurements. Therefore, a free rotation of the fluorophores on a timescale faster than the fluorescence lifetime is aimed at, leading to an average orientation factor $<\kappa^2>=\frac{2}{3}$. Linkers with several carbon atoms are used to assure unhindered rotation of the dye. However, interactions between the dye and the protein may lead to blocking of the free rotation. Fluoresence anisotropy measurements provide information on the rotational flexibility of the dyes and should therefore always be conducted as a control. Fortunately, even a partial blocking of rotational freedom does not significantly alter the average orientation factor. If, for example, one of the dyes cannot rotate at all while the other one is free to rotate, then the average orientation factor

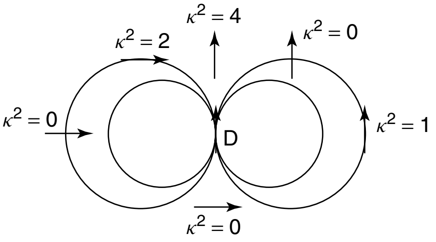

Fig. 20.3 Orientation factors κ^2 for different cases of relative Donor–acceptor placement.

takes the value $< \kappa^2 >= 0.63$ (Berberan-Santos and Prieto, 1988).

In the experiment, the transfer rate is not directly accessible but rather the transfer efficiency, which is the fraction of transferred excitation quanta, and which is related to the distance R as

$$E_t = \frac{1}{1 + \left(\frac{R}{R_0}\right)^6} \tag{13}$$

Whereas in ensemble experiments the transfer efficiency is measured via comparison of donor fluorescence in the presence and absence of the acceptor (e.g. by photo bleaching the acceptor), in single-molecule experiments the fluorescence signals of the donor F_A and of the acceptor F_D are utilized:

$$E_t = \frac{F_A}{\gamma F_D + F_A} \tag{14}$$

The correction factor γ is taking into account the quantum efficiencies of fluorescence of the donor and the acceptor and their respective detection efficiencies. If there is direct excitation of the donor (i.e. not FRET mediated), the acceptor signal needs to be corrected by substraction of that signal. A very robust method to determine the transfer efficiency is based on the fluorescence lifetime of the donor τ_{D0} and τ_{DA} in the absence and presence of the acceptor:

$$E_t = 1 - \frac{\tau_{DA}}{\tau_{D0}} \tag{15}$$

The fluorescence lifetime of the donor without the acceptor is determined in a control sample.

In single-molecule FRET experiments, the photophysics of the dyes has to be treated carefully. Although triplet excursions of the donor simply render the whole donor/acceptor pair dark, the situation is more complex if the acceptor is in the triplet state. If only one excited singlet and triplet state is considered, one would expect that no energy transfer occurs and that all excitation quanta lead to an emission of the donor in this case, resulting in an anticorrelated fluctuation of the donor and acceptor fluorescence. The existence of higher excited states for the acceptor, however, in the singlet as well as in the triplet system, gives rise to other pathways for the excitation energy. In particular, FRET-type energy transfer can result in an excitation of the acceptor to a higher triplet state T_n. Depending on the efficiency of this transfer process, the donor fluorescence may increase, stay constant, decrease, or even completely vanish when the acceptor is triplet shelved (Maus *et al.*, 2001). The latter process is known as *singlet-triplet annihilation (STA)*.

20.2.3
The Dye Molecule as a Dipole

Classically, a dye molecule can be treated as a dipole antenna. Therefore, its absorption and emission have the same anisotropy. Only the component of the electric field parallel to the absorption dipole axis can excite the fluorophore, and the probability curve of photon emission has the same shape as the emission intensity of a dipole antenna. This holds in an isotropic medium as well as in the vicinity of an interface between media with different refractive indices. If a fluorophore is, for example, located close to an interface to a medium with a higher refractive index (imagine a fluorophore in an aqeous surrounding close to a glass coverslip), most of its fluorescence is emitted toward the interface (Figure 20.4). Additionally, the light emitted by a fluorophore is linearly polarized in the dipole direction. The anisotropy as well as the polarization of the emission can be exploited for the determination of the orientation of the dipole in space or even for the relative orientation of the dipoles in a donor/acceptor pair (Hübner *et al.*, 2004).

20.3
Techniques

20.3.1
Signal-to-Noise Considerations

The key prerequisite for succesful single-molecule fluorescence experiments is a high signal-to-noise ratio. The fluorescence signal in single-molecule detection (SMD) is typically the photon count within a given time interval. Owing to the stochastic nature of photon emission, this photon number is Poisson distributed. The noise of the signal therefore is the shot noise of the total number of detected photons. The total number of detected photons is composed of the signal itself and background contributions. The latter can be further divided into background, induced by the excitation laser, and the background signal coming from the detectors in the absence of any source of light, the dark signal.

The laser-induced background originates from elastic Rayleigh and inelastic Raman scattering, as well as from fluorescence in the optical system and the solvent where the molecule under observation is embedded. Its contribution is linearly dependent on the laser intensity. The dark signal, on the other hand, is a constant. The total signal-to-noise ratio can be given by

$$\begin{aligned}\mathrm{SNR} &= \frac{\eta_{\mathrm{det}} \cdot R \cdot T_{\mathrm{int}}}{\sqrt{\eta_{\mathrm{det}} \cdot R \cdot T_{\mathrm{int}} + C_b \cdot I_L \cdot T_{\mathrm{int}} + N_d \cdot T_{\mathrm{int}}}} \\ &= \frac{\eta_{\mathrm{det}} \cdot R}{\sqrt{\eta_{\mathrm{det}} \cdot R + C_b \cdot I_L + N_d}} \cdot \sqrt{T_{\mathrm{int}}} \end{aligned} \tag{16}$$

where R is the emission rate of the fluorophore, T_{int} is the integration time, η_{det} is the detection efficiency, C_b is the constant of proportionality between laser intensity I_L and laser-induced

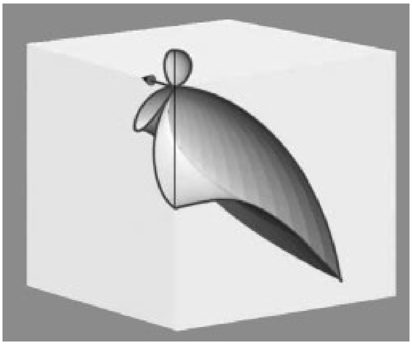

Fig. 20.4 Fluorescence emission characteristics of a dipole close to an interface to a medium with higher refractive index.

background photon rate, and N_d is the dark count rate of the detector.

Saturation of the fluorescence signal leads to an optimum exciation rate for a given integration time where the SNR reaches its maximum, as shown in Figure 20.5.

20.3.2
Wide-Field Fluorescence Microscopy Techniques

In wide-field fluorescence microscopy, the whole field of view of an optical microscope is illuminated to excite fluorescence, and the whole field of view is also imaged onto a camera. The great advantage of wide-field microscopy is that on the one hand, many molecules can be observed in parallel, and that on the other hand, the trace of a moving molecule can be followed. However, the time resolution is limited by the cameras in use.

For single-molecule fluorescence imaging, a very sensitive camera is necessary. If slow processes are to be followed, backthinned cooled charge-coupled device (CCD) cameras are the best choice. These CCDs convert incoming photons into electrons with an efficiency close to unity. However, the readout process of the charges introduces noise of typically a few electrons. Therefore, single photon detection is not possible, and longer exposure times are necessary.

If single photons are to be detected with a camera and a short integration time is wanted, then intensified cameras or electron-multiplying CCDs (EMCCDs) can be used. Intensified CCDs have an image intensifier coupled to the CCD camera. The image intensifier is a multichannel plate photomultiplier (MCP PM) with a phosphor behind the anode. Thus, an impinging photon is first converted into a photoelectron, which is multiplied in the PM, and the electron avalanche is converted back into light. The light from the phosphor is then detected by the CCD. Typical quantum efficiencies of the photo cathodes of image intensifiers are in the 10% to 20% range.

A great breakthrough in camera technology was the introduction of an electron-multiplying or gain register in the CCD. In this register, the single

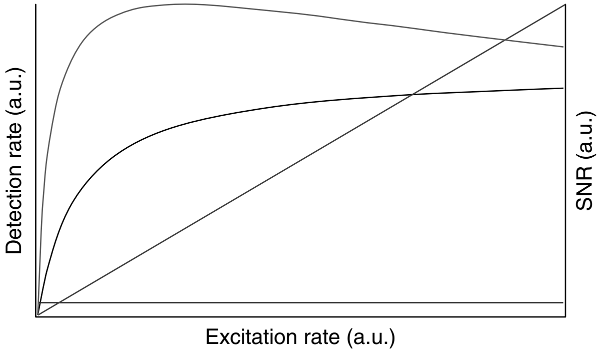

Fig. 20.5 Signal-to-noise ratio as a function of excitation laser intensity according to Eqs (16) and (6) (green). Also plotted are the fluorescence intensity of the single molecule (black), the dark signal (blue), and the laser-induced background (red). (Please find a color version of this figure on the color plates.)

charges are multiplied in an avalanche process principally similar to a PM. Thus, the single electron generated by a single photon is multiplied to a number that is higher than the readout noise and can therefore be detected. EMCCDs have the same high quantum efficiency of photon detection as CCDs close to unity.

The time resolution of a CCD camera is typically limited by the readout process. However, if only a short sequence of images is to be taken, the charges can be first shifted on the CCD chip and subsequently read out. Depending on the size of the image, exposure times in the submillisecond range are possible this way.

With respect to excitation of fluorescence, two different illumination modes can be applied, namely, conventional epifluorescence and total internal reflection (TIR) excitation as discussed in the following sections.

20.3.2.1 Epifluorescence Microscopy

The simplest way to observe the fluorescence of single fluorophores is via the use of a conventional epifluorescence microscope. Here, the whole field of view is illuminated by parallel laser light (Figure 20.6a). Therefore, the laser is focused into the back focal plane of the microscope objective. This technique, however, requires a sample that is thinner than the focal depth of the microscope, since otherwise out-of-focus molecules would give rise to a high background signal. Such thin samples are, for example, molecules tethered on the surface of a coverslip or embedded in a thin polymer film. A cell membrane as well is representing a thin sample, so that epifluorescence microscopy is the method of choice to study, for example, membrane diffusion (Schütz, Kada, Pastushenko and Schindler, 2000).

20.3.2.2 TIRF Microscopy

If the requirement of a thin sample for epifluorescence microscopy is not fulfilled, then illumination of out-of focus molecules can be circumvented by TIR excitation. The excitation laser is totally reflected typically at a glass–water interface and only fluorophores in the evanescent field at the interface are excited. Depending on the angle of incidence and the wavelength of the laser, the evanescent field penetrates approximately 10 nm into the aqueous medium. The small penetration depth is advantegeous with respect to lowering the background, but on the other hand, prevents observation of features further away from the interface.

Two different realizations for total internal reflection fluorescence (TIRF) excitation are used, objective-type TIRF and prism-type TIRF.

In objective-type TIRF, illumination is carried out similar to epifluorescence by

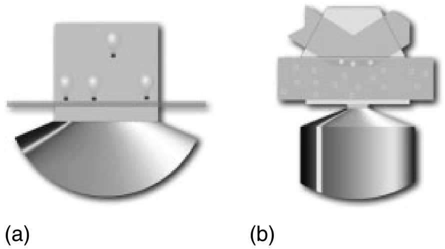

Fig. 20.6 (a) Sketch of epifluorescence and (b) TIRF illumination modes in wide-field microscopy.

focussing the laser in the back focal plane of an oil immersion microscope objective. In contrast to epifluorescence, this focus is offset from the optical axis so that the emerging parallel light is tilted by an angle larger than the critical angle for total reflection at the glass–water interface of 61°. The highest achievable tilt with a numerical aperture (N.A.) = 1.4 oil immersion objective is 67°. Dedicated TIRF objectives have N.A. = 1.45 corresponding to a maximum tilt angle of 73°. The advantage of objective-type TIRF is that the fluorescence is collected through the glass cover slip, in a direction where most of the fluorescence is emitted (cf. Figure 20.4). Thus, a high detection efficiency is assured.

In prism-type TIRF (Figure 20.6b), the laser is directed into a prism and the excitation occurs on the prism surface with TIR. In contrast to objective TIRF, the fluorescence is collected through the aqueous medium. Thus, the detection efficiency is considerably lower. The advantage of prism-type TIRF is the higher flexibility in the choice of the angle of incidence of the laser light.

20.3.3
Confocal Optical Microscopy

The main principle behind confocal optical microscopy invented by Marvin Minsky (1957) is that a point light source and a point detector are both being imaged in the same position in the sample. The point spread function (PSF) of the microscope, that is, the image that is obtained from a point in the sample, therefore is the product of the two PSFs of illumination and detection. Typically, the microscope objective is used for both focusing the laser and detecting the fluorescence in an epi-illumination scheme, and excitation and fluorescence light are seperated in a dichroic beam splitter as can be seen in Figure 20.7. The product of the excitation and detection PSFs defines the confocal volume of about 0.1 fl. The shape of the confocal volume depends on the illumination conditions, but can be approximated quite well by a three-dimensional Gaussian intensity distribution. The advantage of the smaller PSF is not primarily the somewhat higher resolution but rather a considerable reduced background. Laser-induced background signal is in a first approximation proportional to the detection volume. Compared to wide-field microscopy, this volume is reduced by a factor of about $2^{3/2}$.

To obtain an image, the confocal volume is raster scanned across the sample. In contrast to wide-field microscopy, where all points of the image are obtained in parallel in a single exposure, in confocal microscopy the image is built in a serial manner, point by point. This results in a drastically prolonged time to record a single image as compared to wide-field microscopy.

To build the image, either the sample or the confocal volume is moved. For sample scanning, piezo-driven scan stages are used, whereas beam or laser scanning is realized by galvanometer mirror scanners. For the latter, a telecentric lens system generates an image of the scanning mirrors in the back focal plane of the microscope objetive. Thus, a tilt of the scanning mirror results in a shift of the confocal volume in the sample.

Sample scanning has the clear advantage that the light propagates always on the optical axis through the microscope objective. Therefore, aberrations due to tilt of the beam with respect to the optical axis like koma or astigmatism are

avoided. The allowed size of the image is only limited by the scan range. In contrast, in beam-scanning microscopes the size of the image is limited by the microscope objective. On the other hand, beam scanning has also several advantages: The achievable scan speed is considerably higher, the field of view can be changed by using microscope objectives with different magnifications, and the sample can be mounted in a cryostat.

The point-like light source required for confocal imaging is realized either by the use of an excitation pinhole or by feeding the laser through a single-mode optical fiber. A fiber typically guarantees a perfect Gaussian mode, whereas a pinhole is advantegeous with respect to polarization control.

The other element defining the confocal volume is the detection pinhole. For single-molecule fluorescence experiments, the size of the confocal pinhole is chosen with respect to minimal loss of fluorescence signal. A diameter corresponding to the diameter of the airy disk turned out to be a good choice.

Key elements of the confocal microscope are the dichroic or multichroic beam splitter and the emission filters. Although in the past, holographic notch filters were primarily used to block the backscattered laser light, the development of ever better dielectric filters has rendered them a cost-effective alternative. In particular, sputtered dielectric filters confirm this fact with steep edges, high optical density at the laser wavelength, high transimission in the pass band, and their ruggedness. Care should be taken that the filters are subpixel registered, that is, that they do not introduce beam deviations.

The confocal optical microscope is used in two different regimes for single-molecule experiments: In solution experiments, the confocal volume is placed stationary in the sample solution, and freely diffusing molecules lead to fluorescence bursts when they cross it. Thus, distributions of fluorescence properties of the molecules are obtained. If there is dynamics present on a timescale faster than the transit time, this dynamics can be studied. Dynamics on longer timescales, however, is not accessible with this method.

In immobilized experiments, the Brownian motion is prohibited by appropriate immobilization techniques like embedding in a gel or tethering to a surface. The confocal volume is placed on a particular molecule localized earlier by an image scan, and the (transient) fluorescence is recorded. This way, dynamical processes on all time scales can be studied.

20.4
Applications

20.4.1
Protein Folding

The mechanism by which the unstructured polypeptide chain of a protein finds its unique structure remains one of the great mysteries in protein biophysics. It is believed that there is no single pathway but rather a bunch of ways from the ensemble of unstructured chains to the final three-dimensional structure. This heterogeneity is an appealing target for single-molecule studies. Its ability to resolve subensembles allows for the study of the unfolded state and of folding kinetics and chain dynamics under equilibrium conditions, where either of the folded or unfolded state is weakly populated.

20.4.1.1 **The Unfolded State**

The best-studied subject in protein folding with single molecules is the unfolded state. The interest in the unfolded state arises from the idea that knowledge about its conformation and dynamics under nativelike conditions provides information about the initial steps on the folding pathway. In the first experimental single-molecule FRET study, the well-investigated protein chymotrypsin inhibitor 2 was specifically labeled with tetramethylrhodamine as the donor and Cy5 as the acceptor (Figure 20.8a) (Deniz *et al.*, 2000). The confocal volume was placed in the sample solution, and Brownian diffusion gave rise to a burst of fluorescence each time a molecule was passing by. Each burst was analyzed with respect to the transfer efficiency and added to a histogram. This way, a distribution of FRET efficiencies is obtained. The histograms shown in Figure 20.8b consist of two distinct, rather broad peaks, corresponding to the folded state (high transfer efficiency) and the unfolded state (low transfer efficiency). From the areas under the peaks, the concentrations of the folded and unfolded states can be directly obtained. Strikingly, the center position of the unfolded peak shifts to higher transfer efficiencies with decreasing denaturant concentration, as can be seen in Figure 20.8c. This shift is indicative of a compaction of the unfolded polypeptide chain under nativelike conditions.

Using the same methodology, Schuler *et al.* studied the folding transition of the cold shock protein from *Thermotoga maritima* (Schuler, Lipman and Eaton, 2002). Csp*Tm* was labeled with a donor and an acceptor dye (Figure 20.9a and b), and single-molecule bursts were analyzed for their FRET efficiency and compiled

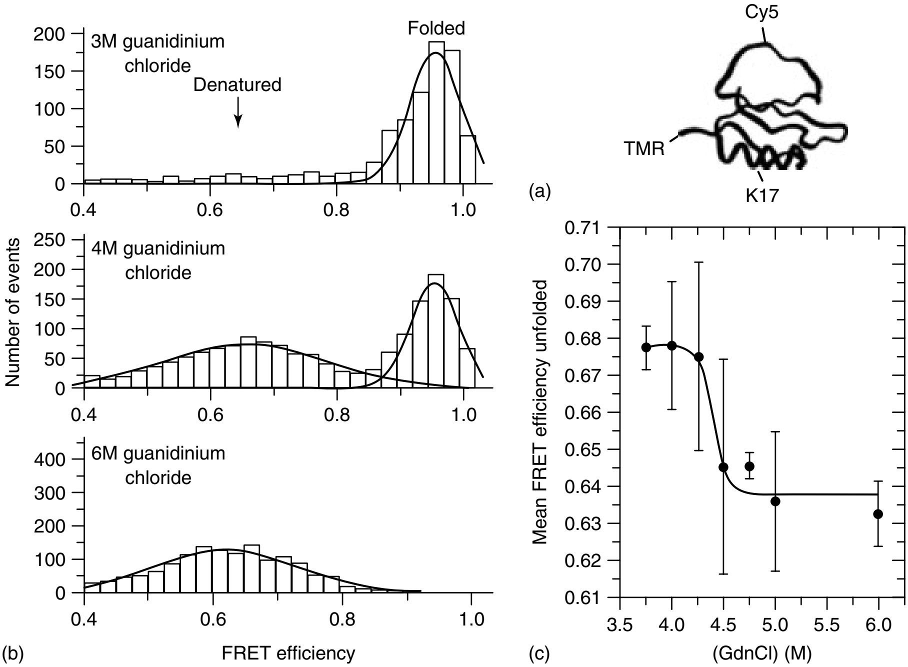

Fig. 20.8 (a) A structural sketch of chymotrypsin inhibitor 2 showing the labeling sites with tetramethylrhodamine as the donor and Cy5 as the acceptor. (b) Energy transfer histograms for different GdnCl concentrations. (c) Mean FRET efficiency as a function of denaturant concentration. Adapted from Deniz *et al.* (2000).

in a histogram shown in Figure 20.9c. Again, a compaction of the unfolded chain is observed (Figure 20.9d). Furthermore, from the finding that the width of the transfer efficiency distribution is shot noise limited it can be concluded that the reconfiguration time is considerably shorter than the transit time of the molecule through the focus. Thus, an upper limit for the reconfiguration time for the polypeptide chain is obtained, which allows for estimating a lower bound for the energy barrier height between the unfolded and folded states of the protein.

Recently, Hofmann et al. have studied the influence of different denaturants, namely, guanidinium chloride (GdnCl) and urea, on the collapse of the unfolded chain of the model protein barstar (Hofmann *et al.*, 2008). Using the same FRET pair as Schuler *et al.*, the subpopulation-resolved transfer efficiencies were measured as a function of denaturant concentration. It was found that for low denaturant concentrations, the chain is more compact in GdnCl than in urea. One possible explanation for this finding is that the charges in the polypeptide chain are shielded in GdnCl, thus reducing electrostatic repulsions. This interpretation was further evidenced by unfolding data in urea and the addition of salt, showing a clear compaction of the chain on addition of salt. This experiment shows that electrostatic interactions are important determinants of the conformation of the unfolded peptide chain.

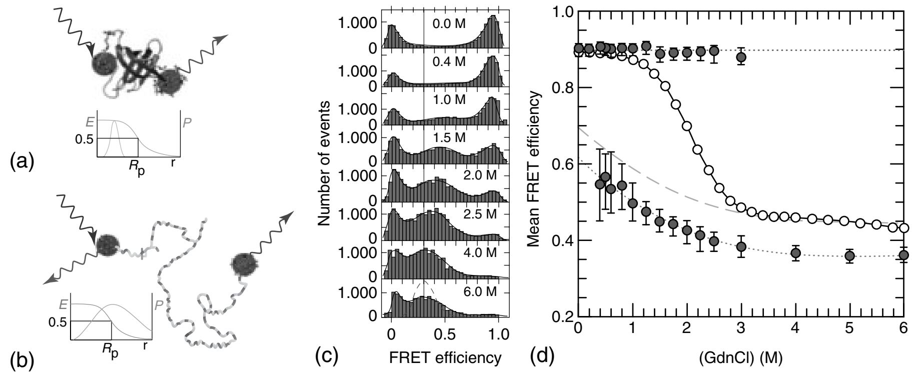

Fig. 20.9 The doubly labeled protein CsP*Tm* in the (a) folded and (b) unfolded states additionally showing the label-distance distribution and the distance-dependent FRET efficiency. The donor dye AlexaFluor 488 is shown in green and the acceptor AlexaFluor 594 in red. (c) The distributions of apparent FRET efficiencies of single CsP*Tm* molecules diffusing through the confocal volume for increasing GdnCl concentrations. The three peaks can be associated to (from left tp right) molecules missing an acceptor dye, unfolded, and folded molecules, respectively. (d) Mean transfer efficiencies derived from the histograms for the folded and unfolded population. The open circles are from ensemble measurements. Adapted from Schuler, Lipman and Eaton (2002). (Please find a color version of this figure on the color plates.)

The dynamics of the unfolded chain of donor/acceptor labeled CspTM was directly monitored by Nettels et al. with a sophisticated technique based on a Hanbury-Brown and Twiss detection scheme (Nettels *et al.*, 2007). With this method, the intensity autocorrelation function can be measured down to the nanosecond timescale by circumventing the dead time of the detectors using a pair of them. Chain dynamics associated with fluctuations of the donor–acceptor distance correspondingly results in intensity fluctuations of the donor and acceptor. Thus, the intensity autocorrelation shows a decay on the timescale of the fluctuations. Figure 20.10 shows the donor and acceptor interphoton time histograms for the unfolded population featuring photon antibunching on the nanosecond timescale typical for a single emitting quantum system. Strikingly, an additional decay of the correlation function is found. The time constant of this exponential decay is 44 ns, being the reconfiguration time of the chain, which is related to the frequency of attempts to cross the energy barrier separating the unfolded and folded states. Thus, single-molecule photon statistics is a valuable tool for the study of chain dynamics associated with the folding reaction.

20.4.1.2 **Single-Molecule Folding/Unfolding Transitions**

A direct observation of folding/unfolding transitions succeeded for the protein adenylate kinase from Escherichia coli, immobilized by encapsulation in surface-tethered vesicles (Rhoades, Gussakovsky and Haran, 2003). The protein is labeled with a donor/acceptor pair, and their fluorescence is transiently recorded as a function of time. To this end, the confocal volume is centered on a vesicle with an encapsulated protein. Surprisingly, rather slow transitions

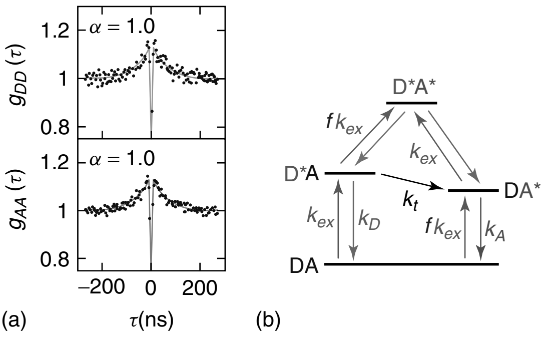

Fig. 20.10 (a) Interphoton time histogram of donor (top) and acceptor (bottom) fluorescence showing antibunching at short times and a correlation on the 100-nanosecond timescale. (b) Photophysical model with the ground states A and D and the respective excited states A* and B*. Fluctuations of k_t lead to the decay in the correlation functions shown in (a). Adapted from Nettels *et al.* (2007).

between the two states are occassionally observed (Figure 20.11a–c). These slow transitions might indicate the search for the folding pathway in the rugged energy landscape between the folded and unfolded state. Further evidence for the existence of local minima in this landscape is provided by the finding of small steps in the transfer efficiency, indicating partial folding/unfolding events (Figure 20.11). Furthermore, there is a broad distribution of step sizes for both folding and unfolding transitions (Fig. 20.11e). The stochastic nature of the walk on the energy landscape renders it impossible to observe those in ensemble experiments, clearly pinpointing the advantage of the single-molecule approach.

20.4.2

Enzymes

Single-molecule investigations of enzymatic activity are very appealing for a number of reasons. The most obvious one is common to all single-molecule experiments: the study of heterogeneity. Single-molecule fluorescence, on the other hand, also allows measurements of enzyme kinetics under equilibrium conditions. Furthermore, under nonequilibrium conditions, the system may remain stationary, that is, the concentration of educts and products stays almost constant, because of the low enzyme concentration in single-molecule studies. Eventually, the investigation of conformational changes associated with enzymatic activity may elucidate the mechanisms of catalysis.

20.4.2.1 **Static and Dynamic Heterogeneity**

The prototype experiment for the study of static and dynamic heterogeneity in enzyme activity was performed by Sunney Xie and coworkers with the enzyme cholesterol oxidase (COx) (Lu, Xun and Xie, 1998). Flavin adenine dinucleotide (FAD), the cofactor of this enzyme, is fluorescent in the oxidized and nonfluorescent in the reduced state. During enzymatic turnover, FAD switches between the oxidized and reduced states.

The COx molecules are embedded in an agarose gel (Figure 20.12a), thus freezing their translational mobility while preserving rotational freedom. The latter is very important to avoid fluctuations in the fluorescence signal owing to slow reorientation. The confocal volume was centered at one COx molecule, and FAD fluorescence recorded as a function of time.

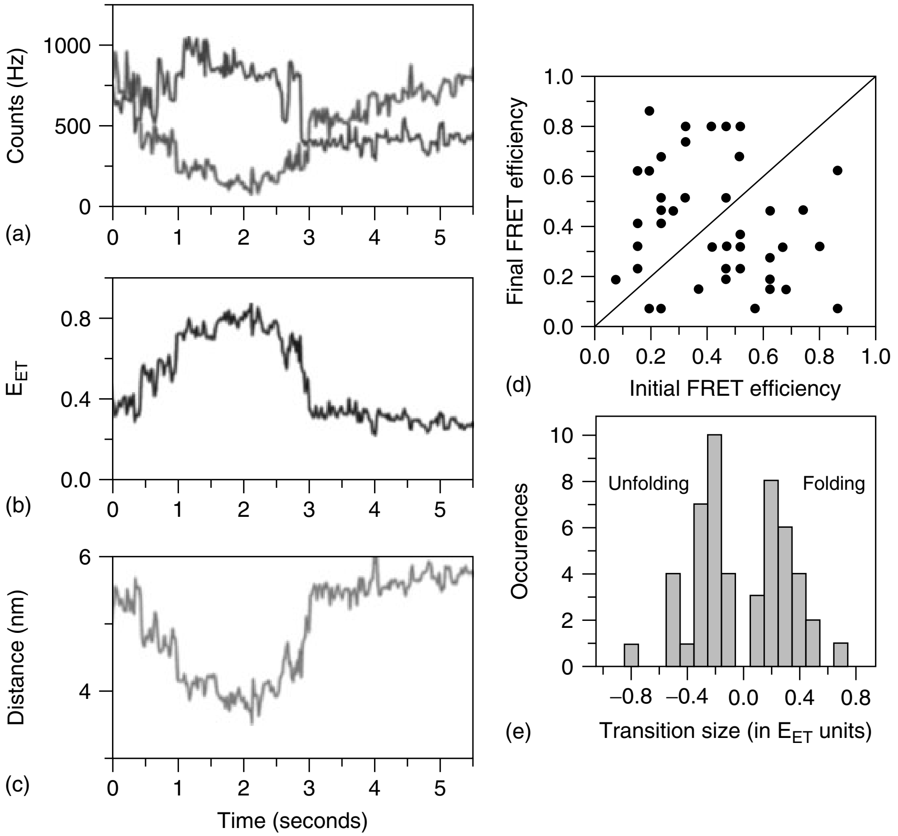

Fig. 20.11 (a) Transient donor and acceptor intensities for a single adenylate kinase molecule inside a vesicle. The anticorrelated behavior is indicative of a change in FRET efficiency shown in (b), which in turn can be related to a donor–acceptor distance change shown in (c). (d) Distribution of initial/final FRET efficiencies for folding (below the diagonal line) and unfolding (above the diagonal line) transitions. (e) Distribution of FRET efficiency step sizes of folding/unfolding. Adapted from Rhoades, Gussakovsky and Haran (2003).

Binary jumps in the transient fluorescence intensity in Figure 20.12b are indicative of cycling between the fluorescent and nonfluorescent states of FAD. Therefore, the catalytic activity is directly accessible, where one turnover is just one cycle of high and low fluorescence intensity. The steady-state kinetics can be obtained from the distributions of the on and off states of the fluorescence corresponding to the two modifications of FAD within the reaction cycle. Hence, both half-cycles of the reaction can be analyzed within one single-molecule experiment.

Strikingly, there is a rather broad distribution of the on times corresponding to the FAD reduction half-cycle for 33 CO*x* molecules, indicative of static disorder, that is, different enzymatic activities of the different enzyme molecules. Now the question arises if there is also dynamic disorder, which is a fluctuation in enzymatic activity over time. To adress this

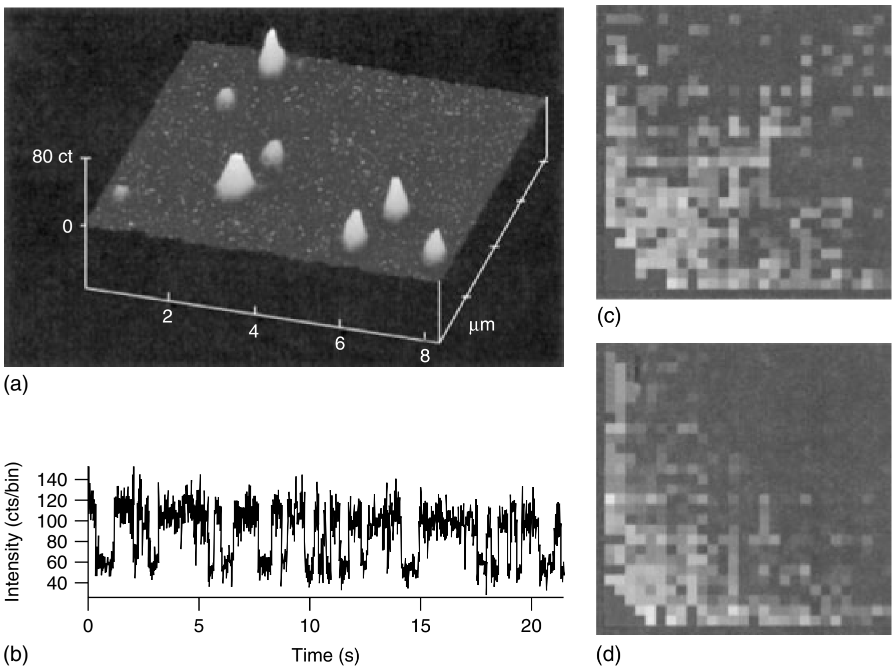

Fig. 20.12 (a) Fluorescence intensity image showing single COx molecules. (b) Transient fluorescence intensity of a single COx molecule showing binary on/off behavior . (c) and (d) 2D conditional probability distribution for a pair of two adjacent on times and for a pair of on times separated by 10 turnovers. Adapted from Lu, Xun and Xie (1998).

question, pairs of on times separated by a defined number of turnovers are considered and their conditional probabilities calculated. If an on time of a certain duration is with a high probability followed by an on time of the same length after this certain number of turnovers, the conditional probability is high. If there is no correlation between the length of the pairs of on times separated by the number of turnovers, the conditional probability is low. In a two-dimensional conditional probability distribution histogram a diagonal feature is indicative of a correlation of the on time durations of on states. Such a feature is visible for adjacent on times (Figure 20.12c), but absent for on times separated by 10 turnover cycles (Figure 20.12d). A covariance analysis even allows for determination of the characteristic timescale for the fluctuations in catalytic activity. Fluctuations of the spectral mean of FAD emission in the absence of cholesterol on the same time scale are interpreted in terms of conformational changes, with the simplest model of interchange between two conformational substates.

Edman and Rigler have used a similar approach for the study of catalytic activity of the enzyme horseradish peroxidase (Edman and Rigler, 2000). Using dihydrorhodamine 6G as a substrate that is nonfluorescent, the catalytic turnover can be followed by the generation of the product rhodamine 6G. The memory landscapes of different proteins are indicative of non-Markovian behavior. Furthermore, oscillations in these memory landscapes can be interpreted by a model where the molecule passes through a number of inactive (conformational) substates and one active substate.

Recently, static heterogeneity was also reported for single enzyme molecules using a fluorescence-based activity assay with much larger statistics (Rissin, Gorris and Walt, 2008). However, this experiment was based on the determination of product concentration and is therefore not capable of accessing the turnovers of a single enzyme molecule.

20.4.2.2 **Conformational Changes and Catalytic Activity**

The prime example for the study of conformational dynamics of single enzyme molecules is the rotation of F_0F_1 ATPase (Kagawa and Racker, 1966). This membrane protein synthesizes adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and phosphate driven by a proton gradient across the membrane. The stepwise rotary motion was first directly observed by videomicroscopy of a fluorescent actin filament attached to the F_1 part (Noji *et al.*, 1997). Although ensemble methods are able to show that rotation occurs, only single-molecule experiments allow for resolution of a sequence of steps. After this key experiment, the rotation was investigated by different single-molecule fluorescence methods (Rondelez *et al.*, 2005; Yasuda *et al.*, 2003; Yasuda *et al.*, 2001; Hisabori, Kondoh and Yoshida, 1999; Iino *et al.*, 2005; Itoh *et al.*, 2004; Masaike *et al.*, 2000; Nishizaka *et al.*, 2004; Adachi *et al.*, 2007; Kaim *et al.*, 2002; Börsch *et al.*, 2002; Diez *et al.*, 2004; Zimmermann *et al.*, 2006; Steigmiller *et al.*, 2004). Kaim et al. show by polarized detection the stepwise rotation of complete F_0F_1 ATPase from *Propionigenium modestum* both in synthesis and hydrolysis (Kaim *et al.*, 2002). To this end, the c subunit was labeled by a fluorescent dye with rigid joining (Figure 20.13a). From the transient fluorescence detected in two channels corresponding to orthogonal polarizations, the polarization P can be calculated according to

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \tag{17}$$

The time-dependent polarization in the presence of ATP and Na^+ in Figure 20.13b shows stepwise changes between three levels, indicating rotational motion in three steps. A data analysis by means of the autocorrelation function of the transient polarization revealed that a model with three pairs of 90°/30° steps as proposed by Yasuda *et al.* (2001) was most consistent with the data.

Single-molecule FRET experiments were also able to show stepwise rotation of F_0F_1 ATPase. Incorporating doubly labeled ATPase (Figure 20.13) in liposomes freely diffusing in solution, Diez et al. recorded FRET efficiency transients during passage of the liposomes through the focal volume (Diez *et al.*, 2004). Those transients show stepwise changes both in hydrolysis and in synthesis between three levels (Figure 20.13d and e). Strikingly, the order of the levels is reversed in hydrolysis/synthesis, thus elegantly demonstrating the reverse of rotation. Recently, Yasuda et al. were able to identify the transiently populated ATP waiting conformation by single-molecule FRET experiments on immobilized ATPase molecules (Yasuda *et al.*, 2003).

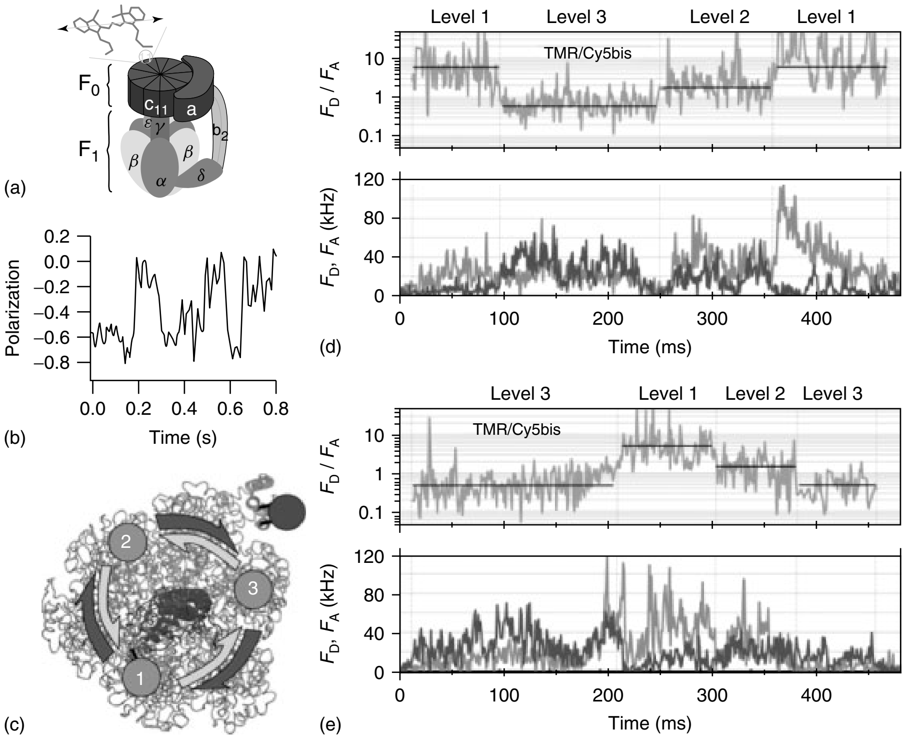

Fig. 20.13 F_0F_1 ATPase labeled at the c subunit (a) shows steps in the polarization transient (b). Donor/acceptor labeled ATPase (c) exhibits jumps between three levels in the ratio between the fluorescence of the donor and acceptor in hydrolysis (d) as well as in synthesis (e) with reversed order. Adapted from Kaim *et al.* (2002) and Diez *et al.* (2004).

The first single-molecule FRET demonstration of conformational dynamics associated with enzymatic activity succeeded with the enzyme *staphylococcal nuclease* (SNase) in the group of S. Weiss (1999). SNase labeled with a donor/acceptor pair showed fluctuations of the transfer efficiency that can be quantitatively analyzed in terms of the autocorrelation function of the transfer efficiency shown in Figure 20.14. The decay in the E_t autocorrelation function can be fit by an exponential with time constants ranging from approximately 10 to 1000 milliseconds, with an average of 41 milliseconds. In the presence of pTp, a known inhibitor of SNase activity, this mean is shifted to 133 milliseconds. Therefore, it can be concluded that the inhibitor affects the conformational flexibility that is essential for SNase function. Via labeling of the SNase with donor and the deoxyribonucleic acid (DNA) substrate with the acceptor, SNase activity can be directly monitored via the association time, which is the time period of high FRET efficiency. A clear difference in association times is observed if the DNA is labeled either at the 5' or 3' end. This difference is in agreement with SNase processivity in the 3' to 5' direction.

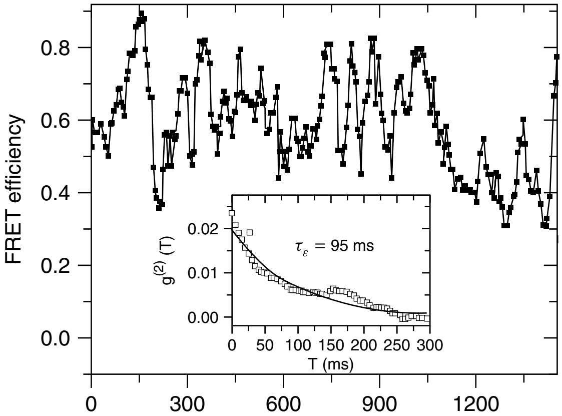

Fig. 20.14 FRET efficiency fluctuations of a single SNase molecule immobilized on a coverslip. The inset shows the autocorrelation function of the the FRET efficiency together with an exponential fit. Adapted from Ha *et al.* (1999).

Quenching of the dye AlexaFluor 488 was exploited for the investigation of conformational transitions of the enzyme dihydrofolate reductase (DHFR) (Zhang *et al.*, 2004). DHFR is a two-substrate enzyme catalyzing the reduction of dihydrofolate (DHF) to tetrahydrofolate (THF) by nicotinamide adenine dinucleotide phosphate (NADPH). To this end, AlexaFluor 488 was specifically attached to the structural loop that closes over the substrates after binding. Single DHFR molecules were tethered on biotynilated cover slips via a biotin–streptavidin–biotin sandwich. In a TIRF illumination wide-field setup, the transient intensities of many DHFR molecules could be recorded in parallel by an intensified CCD camera. On addition of DHF, conformational dynamics manifests itself in intensity fluctuations of the Alexa dye. In the simplest model, DHFR is switching between two conformational states with an opening and closing rate. Thus, using a threshold criterion, open and closed states can be assigned, delivering the dwell times in the respective states. The histograms of the dwell times provide the rates of opening and closing. From the concentration dependence of the closing rate in conjunction with transient ensemble kinetics measurements, a model can be derived where rapid binding of DHF is followed by a conformational change.

Henzler-Wildman *et al.* have investigated the conformational heterogeneity and dynamics of Adk from *aquifex aeolicus* by X-ray crystallography, molecular dynamics simulations, nuclear magnetic resonance (NMR) spectroscopy, and smFRET (Henzler-Wildman *et al.*, 2007). Adk is a two-substrate enzyme catalyzing phosphotransfer between AMP and ATP in the presence of Mg^{2+}. From X-ray crystallography in the presence of the substrates, it is known that a conformational change occurs when the substrates are bound. Adk was specifically labeled with AlexaFluor 488 as the donor and AlexaFluor 633 as the acceptor at the two substrate-binding lids. First, freely diffusing Adk was investigated, and burstwise histograms of the transfer efficiencies were derived. Surprisingly, even in the absence of any substrate Adk shows at least two subpopulations, where one corresponds to the conformation where both lids are opened and the other one corresponds to the closed conformation, which can be concluded comparing the distances from the FRET experiments with crystallographic data. On addition of the inhibitor diadenosin pentaphosphate (AP5A), the equilibrium between the two conformations shifts toward the closed conformation.

To study the dynamics of conformational exchange, labeled Adk was immobilized on a functionalized cover slip via a His_6 tag. Inspite of the considerable noise level that results from the short integration time dictated by the required time resolution transitions between the open and closed states can be observed. The overlap of the transfer efficiency histograms of two conformations renders a single threshold criterion for the discrimination of the two states unusable. Instead, a threshold zone was defined, where a change-of-state required a complete crossing of the zone. After assignment of the open and closed states, respectively, the dwell times in these states are compiled in histograms. From the histograms shown in Figure 20.15a and b the rate constants for opening and closing are derived. The values found for both cases, $k_{\text{open}} = 6500 \pm 500\,\text{s}^{-1}$ and $k_{\text{close}} = 2000 \pm 200\,\text{s}^{-1}$ for the substrate-free and $k_{\text{open}} = 40 \pm 20\,\text{s}^{-1}$ and $k_{\text{close}} = 350 \pm 200\,\text{s}^{-1}$ for the inhibitor-loaded enzyme, turn out to be very similar to the rates of chemical exchange found by NMR.

The assignment of open/closed states based solely on the apparent FRET efficiency is error prone owing to photophysical processes, which may also lead to fluctuations in the apparent FRET efficiency. It needs to be checked explicitly whether anticorrelated intensity changes of the donor and acceptor fluorescence signals occur. Therefore, a correlation analysis was performed. Clear evidence for anticorrelated behavior of donor/acceptor fluorescence intensity is provided by an anticorrelation in the donor/acceptor cross-correlation function as can be seen in Figure 15c. At shorter times, a correlated fluctuation of donor and acceptor fluorescence is found, which is attributed to triplet dynamics of the donor and/or triplet dynamics of the acceptor and efficient STA. A global fit of the three correlation functions, namely, the donor and acceptor autocorrelation and their respective cross-correlation functions, provides the overall rate of distance dynamics and triplet kinetics. The overall rate of distance dynamics of $k_{\text{tot}} = 7000 \pm 2000\,\text{s}^{-1}$ is in good agreement with the rate from NMR and from the states analysis. During catalysis, opening and closing rates of $k_{\text{open}} = 40 \pm 10\,\text{s}^{-1}$ and $k_{\text{close}} = 1000 \pm 500\,\text{s}^{-1}$ are found matching the NMR data on chemical exchange. Taking into account that NMR can only provide information about the occurance and timescale of dynamics, but no spatial information, these experiments nicely demonstrate that single-molecule FRET experiments perfectly complement other biophysical methods.

Single-molecule FRET experiments have also been performed on *E. coli* AdK, where opening and closing rates of $k_{\text{open}} = 120 \pm 40\,\text{s}^{-1}$ and $k_{\text{close}} = 220 \pm 70\,\text{s}^{-1}$ were found for substrate-free Adk (Hanson *et al.*, 2007).

20.5
Conclusions

In recent years, single-molecule fluorescence has proven to be a valuable tool to obtain information on the conformational dynamics and heterogeneity of proteins that is not accessible by ensemble methods. However, the method is still far from being routinely applicable, mostly for problems with photophysics and photochemistry of the dye molecules. There have been several attempts made to improve the photostability of the dyes, but what works out for a particular dye may be even counterproductive for another. More effort has to be made on both synthesizing new dyes with better stability (Weil *et al.*, 2005) and improving the photostability of existing dyes (Rasnik, McKinney and Ha, 2006).

On the other hand, the noisy signal of a single molecule remains a challenge for data analysis, which might be confronted by methods like, for example, Hidden-Markov modeling Markov (2006).

22.1
Introduction

As nicely described by Mouritsen in the prolog of his book "Life as a Matter of Fat," lipids have been traditionally considered to play a fairly nonspecific role in biological systems, being rather dull with respect to those described for proteins and genes (Mouritsen, 2005a). This probably arose from the role assigned to lipids in the well-known Fluid Mosaic model proposed by Singer and Nicholson in 1972 to represent the structure and dynamics of biological membranes (Singer and Nicolson, 1972). In this model, lipids were postulated to be merely structural builders, forming a fluid double layer (bilayer) in which few embedded membrane proteins perform particular functions. This perspective has been changed dramatically, particularly in the recent years, during which the importance of lipids in cell function and health has been increasingly recognized (Mouritsen, 2005a). For example, it is well known that there are no genes coding for lipids as such – only the enzymes for their synthesis. If this is the case, how does a particular biological membrane end up with a particular combination of hundreds of different lipid species assembled in particular molar ratios? Is there a coherent code for lipids (as for genes and proteins) still hidden and waiting to be discovered (Hilgemann, 2003)? Certainly, the answers are not yet known. These aforementioned and still open questions represent in my opinion one of the most interesting unsolved aspects of biological systems.

Lipids comprise a diverse group of compounds (e.g. phospholipids, sphingolipids, sterols, triglycerides, fatty acids) that participate in essential ways in diverse biological processes. Along with proteins, genes (DNA and RNA), and sugars, these molecules are fundamental building blocks of all living matter. For example, it is clear that lipids play a key role as structural components of cell membranes, but, *together* with membrane proteins and sugars. Lipids themselves also serve as energy storage sources, act as receptors (Velter *et al.*, 2007), and participate in diverse signaling pathways in biological systems (Hilgemann, 2003; Won, Singh, and Singh, 2007).

One very distinctive and peculiar property of lipid molecules is the self-aggregation of these molecules in water. This phenomenon is driven by an increase in the entropy of water in the

ISBN: 978-3-527-40702-6

presence of lipids, a phenomenon known as the *hydrophobic effect* (King and Marsh, 1987). In consequence, lipids form complex multimolecular aggregates with characteristic physical properties (e.g. micelles, bilayers, hexagonal, and cubic phases) (Epand, 2007; Seddon and Cevc, 1993). These different structures play different functional and structural roles in biological systems.

Even though many different lipid structures exist in nature, this chapter will deal mainly with bilayer lipid structures. As mentioned above, bilayers are two-lipid-molecule-thick structures that together with particular proteins and sugars comprise biological membranes. Lipid bilayers themselves show different physical properties depending on their composition and the existing environmental conditions (e.g. temperature, pH, ionic strength). Correspondingly, the remarkable diversity of the molecular species present in biological membranes (lipids, proteins, and sugars) generate a broad range of physicochemical properties that are generally connected with membrane function. Connected to this, the compositional ratio between lipids and proteins is an important parameter to take into account (Marsh, 2008).

Despite the fact that the classical picture of a biological membrane includes a lipid bilayer with few diffusing proteins (Fluid Mosaic Model, see above), it is fair to also say that in many cases biological membranes more resemble proteins sheets with embedded lipid bilayers (the protein–lipid ratio is high). These two last pictures represent extreme cases of a broad range of different compositional possibilities existing in biological membranes and must be taken into account when reductionist approaches are considered.

Given the compositional complexity of biological membranes, reductionist approaches are normally used in order to explore physical (structure and dynamics) and chemical properties of membranes (i.e. the field of membrane biophysics). For example, several model membrane systems (presented in Section 22.3) composed of key lipid species, with or without particular membrane proteins, have been extensively studied for many decades. By using such model lipid systems one can tune, for instance, the membrane compositions going from a very simple lipid mixture to lipid mixtures extracted from biological membranes, or even generate these model systems with the full composition of the native biological membrane (Baumgart *et al.*, 2007; Bernardino de la Serna *et al.*, 2004; Montes *et al.*, 2007). The possibility of systematically increasing the membrane compositional complexity makes it possible to perform interesting comparative studies using an array of different experimental techniques, under very well-controlled and specific environmental conditions (Bagatolli, 2006; Baumgart *et al.*, 2007). Studies performed in theses model systems include lipid–lipid and also lipid–protein and lipid–DNA interactions (Section 22.4). The information obtained from these studies not only provides important foundations about the lateral structure of biological membranes (discussed in Section 22.5) (Silvius, 2005a, 2003; Simons and Vaz, 2004), but also some interesting applications of the lipid model systems over a very broad range of fields (discussed in Section 22.6) (Lasic, 1998). For example, reports regarding the delivery of substances using liposomes are extraordinarily wide-ranging with important applications in science and industry, including molecular biology, biophysics, immunology, cosmetic, pharmaceutical, and food sciences, as well as medical applications (Lasic, 1998). The breadth of liposome applications is such that these lipid entities are also used in marine fish larviculture to encapsulate lipids and amino acids in order to feed the live organisms used for fish larvae food (Barr and Helland, 2007)!

The aim of the following sections is to describe different model lipid systems and some of their applications, as well as a historical perspective of the lipid model systems, information about preparation methods, and some examples of their use in basic sciences and technology. This chapter represents a selective and personal viewpoint about the use of lipid model systems and is not intended to present an exhaustive review of results obtained in the many different and specialized topics involving lipids. The enormous amount of information already reported in the literature would make it impossible to summarize it all in one chapter, as reflected in the fact that the word lipid presently retrieves more that 800,000 citations in PubMed!

22.2
Historical Perspective: Lipid Model Systems

Lipid model systems help us to understand the basic structural and dynamic aspects of biological membranes. From a historical perspective the earliest reports of lipid model systems are, in modern terms, monomolecular lipid films spread at the air–water interface, that is, so-called Langmuir films. The earliest record (reported as oil films floating in water) comes from cuneiform-written Babylonian clay tablets from the Hammurabi period (eighteenth century BC) (Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001). Babylonians used it as one of their forms of divination, based on pouring oil on water and observing the shapes formed with the spreading of the oil. This application was also used in Greek, Chinese, and ancient Japanese cultures (Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001). The most cited report about applications of lipid films is perhaps the calming effect of ripples on the water surface caused by spreading oil, which was already observed by sailors in ancient times and described by Plutarch, Aristotle, and Plinius (Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001). Pouring oil to calm stormy seas is believed to have come from the period 429–651 AD (Fulford, 1968). The scientific investigation of this phenomenon (i.e. using the scientific method) started in Franklin, Brownrigg, and Farish (1774), followed by contributions Pockels (1894), as reported by Rayleigh (1899) and Langmuir provided the first evidence of the monomolecular nature of the films in 1917 (Langmuir, 1917). Such monomolecular films are also known as *Langmuir–Blodgett* films due to the first detailed description of sequential monolayer transfer to a solid support by Blodgett (1935). The term *Langmuir film* is normally reserved for a floating monolayer at the air–water interface while Langmuir–Blodgett films refer to monomolecular films supported in a solid substrate. Incorporation of a transmembrane protein into a supported monolayer was first reported by McConnell in 1983 "... to study specific binding of cytotoxic T cells to well-defined model membranes" (Nakanishi, Brian, and McConnell, 1983). This work was published almost 50 years after Blodgett's contribution. Additionally, an extensive characterization of the lateral structure of lipids using this model system was reported by the McConnell laboratory (McConnell, Tamm, and Weis, 1984). Successive reports about formation of supported lipid *bilayers* on solid supports from Langmuir films were first reported between 1983 and 1985 (Tamm and McConnell, 1985; Tancrede, *et al.*, 1983). Supported planar bilayers are currently used to study a broad range of scientific and practical applications of membrane-related phenomena (Sackmann, 1996) and thus constitute an essential bilayer model system.

Langmuir films were used in a historically "key" experiment connected to our contemporary vision of a biological membrane. In 1925, two Dutch physicians, E. Gorter and F. Grendel, compared the area of "total" lipid extracts from erythrocyte membranes, measured in a Langmuir trough, with the average surface area of red blood cells (Gorter and Grendel, 1925). In their paper the authors report that "... cromocytes of different animals are covered by a layer of lipoids just two molecules thick." Disregarding the fact that lipid bilayers are not biological membranes and a pair of compensating experimental mistakes[1] are present in this article (Bar, Deamer, and Cornwell, 1966), the relevance of the authors' observation cannot be underestimated. The last was the first experimentally supported statement that cell lipids are arranged in a bilayer configuration (Przestalski *et al.*, 2000).

Liposomes (formed by most phospholipids including some sphingolipids when dispersed in aqueous solutions) can be defined as *spherical vesicles*, essentially an aqueous core surrounded by a lipid bilayer. The discovery of liposomes is attributed to (Bangham and Horne, 1964). In their classical paper they provide clear evidence, using electron microscopy, suggesting that dispersion of phospholipids in water formed such baglike structures. In the same paper they argue for first time that the integrity of a bimolecular leaflet of phospholipids depends as much on the presence of water as it does on the precise composition and structure of the participating lipid molecules (Bangham and Horne, 1964). The fundamental structure of this model lipid system agrees very well with the structure and some of the physical properties (e.g. the permeability) proposed previously in earlier models of biological membranes, for example, Gorter and Grendel, and especially that of Danielli and Davson (Danielli and Davson, 1935; Gorter and Grendel, 1925; Robertson, 1981). Subsequent reports from Bangham's laboratory show that these entities are indeed osmotically active, and much more permeable to water than to simple ions or glucose, also demonstrating that the sign and magnitude of the surface charge seemed to determine their relative permeability to cations and anions (Bangham, 1993). During this period, liposomes were adopted as "classic model systems," used to mimic processes occurring in biological membranes, and

---

1) In Gorker and Grendel experiments the area of the red blood cell was underestimated, and due to the roughness of the extraction techniques used at that time they did not extract all the lipids from the erythrocyte membrane. The interesting remark is that the area occupied by the proteins was not considered in their experiments, since there was no concept about integral membrane proteins at that time.

became key players in an enormous range of biotechnological process (Lasic, 1998). Although the credit for discovery of lipid vesicles is given to Bangham and Horne, reports about the colloidal behavior of lecithin and other phospholipids can be found much earlier in literature (Lasic, 2000; Segota and Tezak, 2006). In fact, hydration of dried extracts of lecithin from egg yolk or brain and the subsequent formation of myelin figures (as happens during liposome preparation) were documented in Neubauer (1867); Virchow (1854). Additionally, detailed description of lipid solutions as colloidal systems were obtained during the early 1920s (Lasic, 2000). However, it took more than 100 years and an electron microscope (Bangham and Horne, 1964) to realize that these lipid colloidal suspensions are indeed closed lipid bilayer structures encapsulating the same liquid medium in which they freely diffuse (Lasic, 2000).

Other colloidal suspensions composed of amphiphilic substances (e.g. fatty acids or their salts; lysolipids) are called *micelles*. Micelles are particular aggregates of surfactant molecules dispersed liquid media. A typical micelle in aqueous solution forms an aggregate with the hydrophilic "head" regions in contact with surrounding solvent, sequestering the hydrophobic tail regions in the micelle center. Upon addition of an organic solvent, these micelles can swell, and if the amount of organic solvent exceeds that of the water, the surfactant molecules can invert to form inverted micelles. Micelles are closely connected to soaps, since solutions of these compounds in water will likely contain these structures. Even though the earliest recorded evidence of the production of soap-like materials dates back to around 2800 BC in ancient Babylon (Willcox, 2000), structures and physical properties of micelles were not scientifically studied until the beginning of the twentieth century. Pioneering work with micelles was carried out by James William McBain at the University of Bristol (Rideal, 1953). As early as 1913 he postulated the existence of "colloidal ions" to explain the good electrolytic conductivity of sodium palmitate solutions (McBain, 1913). Micelle formation is essential for the absorption of fat-soluble vitamins and lipids in biological systems. Bile salts formed in the liver and secreted by the gall bladder allow micelles of fatty acids to form, allowing the absorption of lecithin and lipid soluble vitamins (A, D, E, and K) by the intestine. Besides the scientific interest in performing basic types of scientific studies, micelles have a major technological application as emulsifiers (e.g. detergents) with special applications, for example, in emulsion polymerization (Capek, 2001).

Related to freestanding bilayer model systems (e.g. liposomes), a beautiful technique for preparing credible model bilayers using lipid molecules, the so-called black lipid membrane (BLM), was introduced in Mueller *et al.* (1962). This system consists of a freestanding bilayer (generally composed of lipids and proteins) formed across a hole in an inert solid support (Teflon, for example) (Tien and Ottova-Leitmannova, 2003a; Winterhalter, 2000). The name of this model membrane system is connected to previous observations of Newton (Newton, 1704) of black spots in single soap films (the so-called Newton Black films) (Mueller *et al.*, 1962; Tien and Ottova-Leitmannova, 2003a). These black spots observed in film of soaps correspond to bimolecular soap leaflets that are the limiting unit of the smectic, mesomorphic soap phase (Mueller *et al.*, 1962). This conclusion was based on experimental observations of Johonnott, Perrin and Bragg during the 1900–1940 period (Bragg, 1939; Johonnott, 1899, 1906; Perrin, 1918). The same black spots are observed during formation of lipid bilayers under water (the BLMs) (Tien and Ottova-Leitmannova, 2003a). As the film starts to thin out, colored reflections are observed and finally a gray–black spot starts to spread over the film. This annealing is due to the interference of the reflected light from the water–lipid and phase-shifted light from the underlying lipid–water interface, which becomes destructive as the pathway through the membrane and back becomes negligible in comparison to the wavelength (Winterhalter, 2000). From a historical perspective and since the early 1960s, BLMs have become a key bilayer model system to measure transport-associated phenomena across membranes. For example, this model system has been extensively used to perform electrophysiological experiments, measuring ion transport across membranes under controlled compositional and environmental conditions (Morera *et al.*, 2007).

22.3
Model Membrane Systems: a Reductionist Approach

The reductionist approach helps us to understand the nature of complex systems by reducing them to the interactions of simplified descriptions of their parts. Since biological membranes are compositionally complex systems, this approach is extensively used to understand the basis of molecular and supramolecular interactions occurring in membranes, including their consequences on structure, dynamics and ultimately their function. Different model membrane systems, composed of representative molecules, are available (Figure 22.1). In view of the fact that the basic structure of biological membranes is strongly related to lipid bilayers, several bilayer model systems have been developed and are broadly used to study membrane-related phenomena.

22.3.1
Lipid Monolayers

Lipid monolayers have a broad application in the basic sciences (e.g. chemistry, biology, physical-chemistry, polymer science to mention a few). This section, however, will only discuss selected examples related to particular applications of lipid monolayers in biologically relevant problems. Even though this model represents ''half of a bilayer'' (one molecule thick), it is still extensively used to mimic basic molecular and supramolecular interactions in membranes. In fact, a particularly broad variety of different lipid molecules (single species or their mixtures) have been studied using this technique (Brown and Brockman, 2007).

Two main types of model systems are generally studied: (i) Langmuir films (at the air–water interface) and (ii) supported lipid monolayers (on mica or other solid supports). Both systems comprise monomolecular film of lipids. For example, studies reported in these systems include (to mention a few) the lateral structure of compositionally different lipid films (Brown and

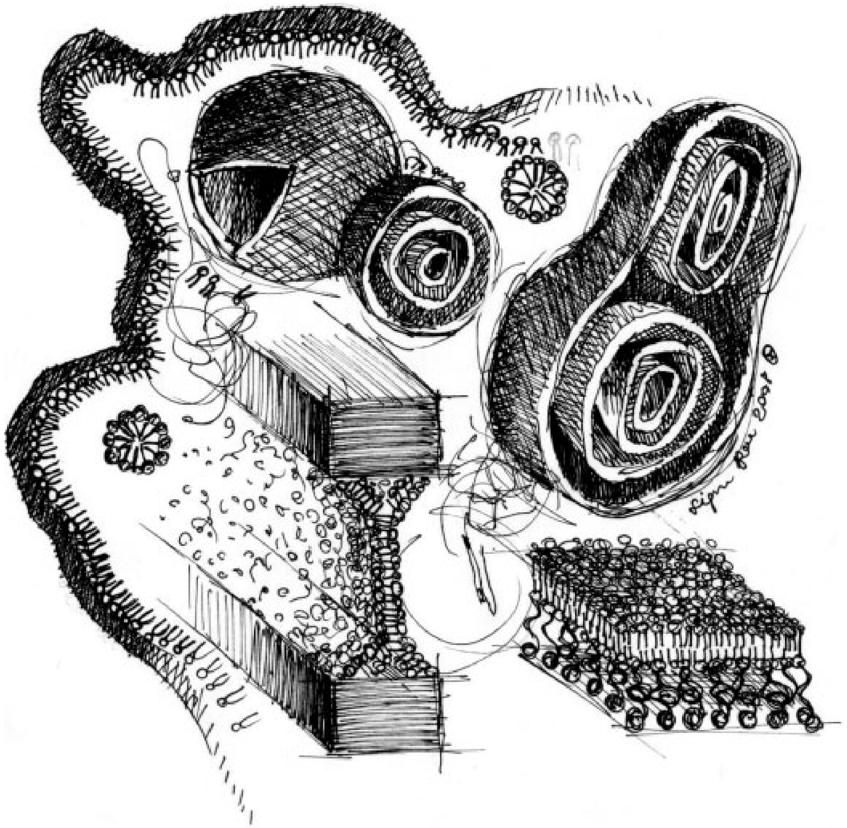

Fig. 22.1 "*Da jeg fandt lykken.*" Sketches with pencil (from Signe Boe private art collection, 2008). Representation of the different lipid models systems.

Brockman, 2007; Maggio, 1994; McConnell, Tam, and Weis, 1984; Norlen *et al.*, 2007), penetration studies of proteins, peptides or other drugs (anesthetics, for example) into a monolayer (Choi, Oh, and Lee, 2001; Fidelio *et al.*, 1986; Maget-Dana, 1999), stability of peptide or protein monolayers (Ambroggio *et al.*, 2004; Churbanova *et al.*, 2006), and enzymatic actions of lipases (Bianco *et al.*, 1991; Pieroni *et al.*, 1990). Studies including rheological, topological, electrical, and mechanical properties of monomolecular films are also accessible using these systems (Brown and Brockman, 2007; Leneweit *et al.*, 2008). For instance, studies of surface pressure and interfacial electrical potential as a function of average cross-sectional molecular area in Langmuir films provide insights into lipid hydrocarbon chain ordering, lateral compressibility/elasticity, and electric dipole effects under various conditions including those that well approximate one leaflet of a bilayer (Brown and Brockman, 2007; Leneweit, *et al.*, 2008).

Importantly, lipid monolayers have a connection with relevant structures existing in biological systems. For example, it is well known that a proteolipid surfactant material exists in our body, for example in the respiratory airways, having important biological functions (Notter, 2000), which is required to avoid lung collapse (by changing the surface tension on the surface of the alveoli) during breathing cycles (Notter, 2000). The organization of lung surfactant at the air–tissue interface has been modeled using monolayers (either Langmuir films or supported monolayers) composed of particular lipid mixtures (with or without proteins), surfactant lipid extracts or the native material (Nag *et al.*, 1998, 2002; Paul, Hassett, and Reiss, 1977; Piknova, Schram, and Hall, 2002; Wang *et al.*, 2007; Yan *et al.*, 2007). In these experiments the role of different components of the material is evaluated under controlled environmental conditions (Casals, 2001; Perez-Gil, 2001).

The preparation of Langmuir films is straightforward and very well described in the literature (Gaines, 1966). Generally, organic lipid solutions are directly spread at the air–water interface in an apparatus that has been traditionally referred to as a *Langmuir trough* (Gaines, 1966). This device consists of a trough, usually made of hydrophobic materials like Teflon to contain the water phase, that includes movable barriers that span the water surface (Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001). Movement of the barriers allows the monomolecular film to be compressed laterally at the air–water interface. The change in the surface tension is generally monitored with a Langmuir balance or a Wilhelmy plate (Cruz and Perez-Gil, 2007; Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001; Gaines, 1966). Plots of the change in surface pressure (π; a measure of the decrease in surface tension, i.e. a two-dimensional analogue of bulk pressure) as a function of the average area per molecule on the aqueous subphase are then obtained at fixed temperature, thus called *pressure-area isotherms* (Cruz and Perez-Gil, 2007; Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001; Gaines, 1966). Under optimized conditions, the monolayer may be amenable to transfer onto hydrophilic/hydrophobic solid supports at different lateral pressures either by the vertical dipping method or horizontal touching methods (Cruz and Perez-Gil, 2007; Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001).

There is an array of different experimental techniques that can be use to study these model systems. For Langmuir films, the most classical measurements perhaps are the pressure–area and surface potential–area isotherms, but also rheological measurements including also measurement based in spectroscopic methods such as Brewster angle, fluorescence microscopy, UV–vis, IR, Raman, and Second harmonic generation (Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001). For supported monolayers, the most commonly applied techniques are atomic force microscopy, ellipsometry, quartz crystal microbalance, grazing angle X-ray diffraction, X-ray and neutron reflectivity, fluorescence microscopy, and near-field microscopy (Dynarowicz-Latka, Dhanabalan, and Oliveira, 2001; Hollars and Dunn, 1998). Interestingly, new applications using mass spectrometry were recently described to ascertain the spatial distribution of molecules on supported monolayers showing phase separated domains (Sostarecz *et al.*, 2004; Zheng *et al.*, 2007). This spatially resolved compositional information is extremely valuable, for example, to define complete phase diagrams of lipid mixtures or localize particular lipid components (or other molecules) into different lipid domains (Kraft *et al.*, 2006). Lastly, different techniques based on computer simulations have also been applied to understand molecular (molecular dynamics simulations approach) or supramolecular (e.g. coarse-grained molecular dynamics approach) details of these model systems (Giner-Casares *et al.*, 2008; Pink, 1984). Structural and dynamic features of particular model systems can be predicted using these computational approaches. In general, the obtained information strongly promotes further development of new experimental strategies in order to corroborate the predictions from the simulations.

22.3.2
Liposomes

As was discussed in Section 22.2, liposomes (lipid vesicles) are one of the most popular model systems containing lipid bilayers. They are classified with respect to their size and the number of lipid lamellaes (single bilayers) existing in their structure (Lasic and Papahadjopoulos, 1995). For example, liposomes containing a single bilayer, known as *unilamellar vesicles*, are classified with respect to size as small, large, or giant. When the liposome is formed from multiple bilayers, the vesicles are called *oligolamellar* or *multilamellar* depending on the number of bilayers present in the lipid aggregate. These lipid structures have been extensively used to study molecular and supramolecular features of lipid–lipid, lipid-protein, and lipid–DNA interactions (Section 22.4 below). In the following subsections, basic descriptions of the model systems and references to protocols for liposome preparation including the experimental techniques used to study liposomes will be addressed.

22.3.2.1 **Small and Large Unilamellar and Multilamellar Vesicles**

The lipid dispersions obtained by directly swelling and shaking dried phospholipid films in aqueous solvent are called *multilamellar vesicles* (MLVs; hand-shaken vesicles) (Lasch, Weissig, and Brandl, 2003). The number of lamellae (bilayers) obtained on these particular structures is high, resulting in a very broad size distribution of these preparations ranging from hundred of nanometers to several micrometers in diameter. If additional energy is supplied to the system it is possible to destabilize these multilamellar structures and form single bilayer structures (Winterhalter and Lasic, 1993). Small unilamellar vesicles (SUVs) have diameters ranging from 30 to 50 nm and thus represent membrane structures with high curvature (Winterhalter and Lasic, 1993). On the other hand, the large unilamellar vesicles (LUVs) have a diameter in the range of 100–200 nm. The curvature of these aggregates is thus much less pronounced with respect to that observed in SUVs (Winterhalter and Lasic, 1993).

A large amount of information is available in the literature regarding the different methods for vesicle preparation, including mechanisms of vesicle formation (Lasch, Weissig, and Brandl, 2003; Lasic, 1988; Lasic and Papahadjopoulos, 1995; Mozafari, 2005; Segota and Tezak, 2006; Szoka and Papahadjopoulos, 1980;

Walde and Ichikawa, 2001). The preparation methods can be categorized as those: (i) that start from dry lipid films, (ii) methods that use micelle-forming detergents (detergent depletion methods), (iii) that are based on mixing nonaqueous lipid solution with aqueous solution (solvent injection method), and (iv) that use emulsions containing water-immiscible solvents as starting systems (Lasch, Weissig and Brandl, 2003; Lasic, 1988; Mozafari, 2005; Ollivon *et al.*, 2000; Szoka and Papahadjopoulos, 1980; Walde and Ichikawa, 2001). Generally, MLVs are an intermediate step in the formation of unilamellar vesicles (e.g. LUVs or SUVs) from dried lipid films. In these cases solutions of MLVs are subsequently treated, for example, using sonication, freeze-thawing cycles, or extrusion through polycarbonate filters of well-defined pore size. The sketch shown in Figure 22.2 represents some of the aforementioned methods used to generate liposomes.

In preparing vesicles (particularly when the starting point involves dried lipid films) it is important to keep in mind that temperatures above the lipid gel–fluid phase transition temperature (T_m) must be used during vesicle formation. The lipid layers in the gel phase have particular mechanical properties (high rigidity, high lateral packing) that do not favor an optimum hydration (swelling) process. Furthermore, when MLVs are

sonicated or extruded at temperatures below T_m, the efficiency of SUV or LUV generation is extremely low (Lasch, Weissig and Brandl, 2003; Lasic, 1988; Mozafari, 2005; Szoka and Papahadjopoulos, 1980; Walde and Ichikawa, 2001).

Another issue involving liposome preparation is related to trapping particular compounds inside the vesicles. As discussed in the Section 22.1, this procedure has several applications in basic sciences and industry, most popularly related to the delivery of substances (e.g. enzymes, drugs, vitamins, or other biological compounds, chemicals, etc.) into particular systems. The efficiency of trapping compounds into liposomes is a major issue in optimizing the different protocols (Mozafari, 2005; Taylor *et al.*, 2005; Walde and Ichikawa, 2001). Generally, this entails only slight modifications of the methods summarized in Figure 22.1. The reader can find additional information about these preparation methods in excellent reviews by Walde and Ichikawa (2001) and Taylor *et al.* (2005) and a book completely devoted to liposome preparation and characterization edited by Torchilin and Weissig (2003).

22.3.2.2 **Membrane Protein Reconstitution in Lipid Vesicles: Proteoliposomes**

Detergent removal methods (Figure 22.2) are of great utility in generating liposomes containing membrane proteins since membrane proteins are generally extracted and purified using detergent based-methods (Ollivon *et al.*, 2000; Seddon, Curnow, and Booth, 2004; Yamaguchi *et al.*, 1981; Yu and Branton, 1976). This particular model system allows protein activity to be evaluated in different lipid environments, permitting for example, correlation of the phase state of the membrane with protein structure/activity. The choice of detergents to perform the reconstitution is critical and is closely related to molecular and supramolecular mechanisms of the vesicle- to-micelle transition (Ollivon *et al.*, 2000). Generally, two common approaches have been used to generate the proteoliposomes: the dilution approach that consists of diluting the protein–detergent mixture with a liposome solution, and first introducing detergents to preformed liposomes before adding the protein–detergent mixture (Rigaud, Pitard, and Levy, 1995; Seddon, Curnow, and Booth, 2004). Also, there are a number of criteria that proteoliposomes should fulfill to be optimized for functional studies, particularly size distribution and uniform distribution of proteins into the liposomes, including the proper protein orientation in the bilayer (Seddon, Curnow, and Booth, 2004). For example, extrusion methods are sometimes applied after detergent depletion in order to achieve homogeneous size distribution (Seddon, Curnow, and Booth, 2004). Vesicles with dimensions corresponding to LUVs represent a common size for this model system although giant-sized proteoliposomes are also used (see next section). Last but not least, lipids and detergents are critical to the stabilization and formation of membrane protein crystals for X-ray diffraction analysis. Comprehensive reviews in this respect are available in the literature (Caffrey, 2003; Nollert, Navarro, and Landau, 2002).

22.3.2.3 **Giant Unilamellar Vesicles**

Many papers have appeared in recent years describing the use of giant unilamellar vesicles (GUVs) as model systems to study different physical aspects of membranes (lateral structure, mechanical properties), not only the effect of lipid–lipid, but also lipid–DNA, lipid–peptide and lipid–protein interactions; (Bagatolli, 2006) and references therein. Giant vesicles are suitable membrane model systems in part because of their size, of the order of a few tens of micrometers which is similar to the size of the plasma membrane of many cells. Single vesicles can thus be directly observed using techniques involving microscopy (such as phase contrast and fluorescence microscopy). Additionally, because experiments are performed at the level of single vesicles, undesired effects of heterogeneity in shape and size and the presence of multilamellar vesicles are eliminated. One significant aspect of using giant vesicles as model systems is the ability to control the molecular composition of the membrane as well as the environmental conditions. For instance, studies of the lateral structure of membranes using giant vesicles as model systems were normally restricted to giant vesicles composed of single lipids species or mixtures with few components (Bagatolli and Gratton, 2000a, 2000b, 1999; Baumgart, Hess, and Webb, 2003; Dietrich *et al.*, 2001; Feigenson and Buboltz, 2001; Kahya *et al.*, 2003; Kahya, Scherfeld, and Schwille, 2005b; Korlach *et al.*, 1999; Sot *et al.*, 2006b; Veatch and Keller, 2002, 2003, 2005b; Veatch *et al.*, 2004). However, as recently reported in the literature, it is also possible to form giant vesicles from natural lipid extracts (Bagatolli *et al.*, 2000; Bernardino de la Serna *et al.*, 2004; Dietrich *et al.*, 2001; Nag *et al.*, 2002) and native membranes (Baumgart *et al.*, 2007; Bernardino de la Serna *et al.*, 2004; Montes *et al.*, 2007; Ruan *et al.*, 2004). Additionally, GUVs containing membrane proteins can also be generated (Bacia *et al.*, 2004; Girard *et al.*, 2004; Kahya, 2006; Kahya, Brown, and Schwille, 2005a; Kahya *et al.*, 2001; Koster *et al.*, 2003) often involving an electroformation method (see below) using proteoliposomes as starting point.

There is no general agreement about "unique" conditions required to obtain giant vesicles mainly because the mechanism underlying giant vesicle formation is still obscure. As a consequence, there are many different methods described in the literature to obtain GUVs (Akashi *et al.*, 1996; Angelova and Dimitrov, 1986; Angelova *et al.*, 1992; Bernardino de la Serna *et al.*, 2004; Girard *et al.*, 2004; Kahya *et al.*, 2001; Moscho *et al.*, 1996; Reeves and Dowben, 1969). However, most of these methods are based on two main experimental protocols: the gentle hydration method, originally described by Reeves and Dowben (1969), and the electroformation method introduced by Angelova and Dimitrov (1986); Angelova *et al.* (1992), see Figure 22.2. Of these two experimental protocols, the electroformation method has the advantage that it provides the more homogeneous population of GUVs, with sizes between 10 and 60 μm in diameter. Additionally, the electroformation protocol requires less time compared to the gentle hydration method (~1–2 hours vs. 12–24 hours respectively) and provides a high yield of giant unilamellar vesicles (~95%) (Bagatolli, Parassasi, and Gratton, 2000; Düzgünes *et al.*, 2003).

Perhaps the main drawback of the use of GUVs as model systems for biological membranes is that low salt concentrations (generally below 10 mM NaCl) are normally required for their preparation using the above-mentioned protocols. This problem has recently been overcome by the introduction of a new electroformation protocol by Pott, Bouvrais, and Méléard (2008). This method, originally developed for single phospholipid species was successfully tested for preparing GUVs from compositionally complex lipid mixtures, including native biological membranes (Montes *et al.*, 2007). Additionally, GUVs containing asymmetric lipid distributions were recently reported by Pautot, Frisken, and Weitz (2003), providing a promising protocol to generate GUVs with different lipid compositions in the two leaflets of the membrane. Generally, bilayer compositional asymmetry is highly relevant since biological membranes are naturally asymmetric. In this method, GUVs are produced from size-controlled drops of water in oil–lipid emulsions and subsequent centrifugation against a lipid monolayer placed in an oil–water interface (Pautot, Frisken, and Weitz, 2003). However, the downside of this method is the impracticality of incorporating membrane proteins into the GUVs. The reader can find additional information about giant vesicles in an excellent review by Menger and Keiper (1998) and a book completely devoted to giant vesicles edited by Luisi and Walde (2000).

22.3.3
Planar Lipid Bilayers

As was stated above, planar bilayers (supported or free standing) are alternative model systems with which to explore the particular interactions among the constituents of biological membranes. One of the most interesting features of these model systems is that they permit generation of highly controlled asymmetric bilayers, that is, with different compositions in the two leaflets (Collins and Keller, 2008; Merkel, Sackman, and Evans, 1989). This aids not only to mimic the asymmetric nature of biological membranes but to improve the reductionist approach. From a compositional perspective these model systems represent an improvement in that include not only lipid but also membrane proteins or peptides. These systems are generally utilized to perform basic research investigation (lipid–lipid, lipid–protein interactions), and in the particular case of the supported planar membrane they are used in technological applications as biosensors (Sackmann, 1996; Trojanowicz, 2001).

22.3.3.1 Supported Lipid Bilayers

Different types of supported bilayers can be constructed (Sackmann, 1996), including (i) integrated bilayers with the inner monolayer fixed to the substrate either covalently or by ion bridges; (ii) freely supported protein bilayers separated from the substrate by ultrathin water layers (~10 Å); (iii) bilayers resting on ultrathin, soft hydrated polymer films; and (iv) freestanding bilayers resting on the aforementioned integrated bilayers called *double-supported bilayers* (Leidy *et al.*, 2004b). Consequently, a variety of methods are utilized to prepare these model membranes. Perhaps the most popular method is based on the successive transfer of monolayers using the Langmuir–Blodgett technique, but methods based in vesicle spreading or hydration of dried lipid films on different solid supports are also used (Crane and Tamm, 2007; Leidy *et al.*, 2004b; Rainey and Sykes, 2005; Simonsen and

Bagatolli, 2004; Steinem *et al.*, 1996). Membrane proteins can be incorporated into these models by spreading proteoliposomes (vesicles containing proteins see below) onto solid surfaces (Arora *et al.*, 2000; Ishiguro and Nakanishi, 1984; Slade *et al.*, 2002). Different solid supports are used to fabricate the different model systems, including mica (commonly used since it is atomically flat and very suitable to perform atomic force microscopy experiments), glass, quartz, and gold. Additionally these solid supports can be modified using polymers or other chemicals in order to generate surfaces of particular hydrophobicity or hydrophilicity (Leonenko, Carnini, and Cramb, 2000; Puu and Gustafson, 1997; Sackmann and Tanaka, 2000; Wagner and Tamm, 2000).

22.3.3.2 **Black Lipid Membranes**

The original method to experimentally generate BLMs consists of painting a solution of lipid in an organic solvent onto an aperture separating two aqueous solutions using a special chamber (Mueller *et al.*, 1962). This particular model thus makes it possible to perform experiments in a planar but freestanding bilayer. Several other methods however, have been described to generate BLM, such as brush, dipping, bubble, syringe, and monolayer techniques as detailed in (Tien, 1974; Tien and Ottova-Leitmannova, 2000). In particular, the monolayer technique allows asymmetric membranes to be formed, a feature that is almost unique to planar lipid systems (i.e. even though some methods are available to generate asymmetric liposomes most of the aforementioned liposomes model systems are symmetric). As was briefly mentioned in the historical perspective section, the major application of BLM is related to electrophysiological measurements. This is due in large part to the fact that the BLM experimental setup easily allows the concentration of ions on both sides of the bilayer to be changed, without causing osmotic stress (as in liposomes). In addition, this model allows for the easy incorporation of proteins (by the brush technique for example) to preformed lipid bilayers. In particular, incorporation of membrane proteins (e.g. channels) and peptides in the lipid bilayer and subsequent measurement of electrical signals through the membrane is commonly performed with BLMs. The reader can find additional information and a vast number of applications in the book “Planar lipid bilayers (BLMs) and their applications” (Chapters 11–26) edited by Tien and Ottova-Leitmannova (2003b).

22.4
Lipids and their Interactions with Macromolecules

This section provides a general summary describing some examples of studies of lipid–lipid, lipid–protein, and lipid–DNA interactions, including brief descriptions of the experimental techniques used in these experiments. Since the volume of the literature is very vast only a few specific (but representative) examples will be presented here.

22.4.1
Lipid–Lipid Interaction

Membranes can be classified as soft materials since they are basically structured liquids made of molecules with substantial conformational complexity (Mouritsen, 2005b). In his book "Life as a Matter of Fat" Mouritsen pointed out "... the physical properties of soft materials are largely determined by soft and fluctuating interfaces, the physics of which is dominated by entropy" (Mouritsen, 2005b). As mentioned above, the anisotropic nature of this material offers highly interconnected "observation windows" at several length and time scales. For example, understanding how a liposome can mimic the natural shape of red blood cells provides insight into which features of these soft materials are relevant to interpret the actual shape of a cell (Mouritsen, 2005c). The mechanical properties of these model membranes (e.g. bending modulus) are studied using different techniques such as micropipette manipulation or flickering analysis (Döbereiner, 2000; Mouritsen, 2005b; Nedham and Zhelev, 2000). Since light microscopic techniques are generally used in these experiments the obvious choice of a lipid model system is a giant vesicle.

A detailed understanding of temperature-dependent membrane phase equilibria in compositionally simple model systems (composed of one, two, and three-component lipid mixtures) constitutes another important step toward an understanding of the lateral organization of compositionally complex membranes. To this end, over the last 40 years there has been extensive research to elucidate the presence of particular lipid phases (including their coexistence) in compositionally diverse membranous systems using an array of experimental techniques such as fluorescence spectroscopy, differential scanning calorimetry, infrared spectroscopy, flourescence recovery after photobleaching (FRAP), electron spin resonance (ESR), nuclear magnetic resonance (NMR), quartz crystal microbalance, grazing angle X-ray diffraction, X-ray and neutron reflectivity, to mention a few, that provide important structural and dynamicl information about the organization of lipid membranes (Almeida, Vaz, and Thompson, 1992; Arnold, Losche, and Gawrisch, 1981; Bagatolli *et al.*, 1997; Blume *et al.*, 1982; Bultmann *et al.*, 1991; Caffrey and Hing, 1987; de Almeida, Fedorov, and Prieto, 2003; de Almeida *et al.*, 2005; Lee, 1975; Lentz, Barenholz, and Thompson, 1976a, 1976b; Mabrey and Sturtevant, 1976; Maggio *et al.*, 1986; Parasassi *et al.*, 1993; Schram, Lin, and Thompson, 1996; Shimshick and McConnell, 1973; van Dijck *et al.*, 1977; Vaz, Melo, and Thompson, 1989, 1990). It also includes theoretical treatments using computer simulations (Ipsen and Mouritsen, 1988; Jorgensen and Mouritsen, 1995). In several cases the results have been utilized to construct phase diagrams for different lipid mixtures, providing important thermodynamic understanding of membrane lateral organization phenomena under equilibrium conditions (Silvius, 2005b; Veatch and Keller, 2005a). It is important to note that the experimental techniques mentioned above only provide average values of parameters on the basis of data collected from bulk solutions of many liposomes (e.g. MLVs, SUVs, large oligolamellar vesicles (LOV)s, LUVs) or lipid hydrated multilayers, and hence lack visual spatial correlation of the lateral structural phenomena observed at the level of *single* membranes. Such information is particularly important in cases of compositionally complex membranes, where assigning lipid components as main actors for observing phenomena using the aforementioned experimental techniques (as generally happens in compositionally simpler situations) is complicated. Furthermore, the construction of phase diagrams is generally limited to a maximum of three components, (Veatch and Keller, 2005a) and is thus not applicable to biological membranes.

Visual spatial correlation of certain physical phenomena, reflected at the nano- and micrometer scales, is provided by microscopy techniques such as fluorescence microscopy or atomic force microscopy. The latter provides nanometer lateral resolution and Ångstrom resolution vertically, allowing visualization of phase separated lipid domains using supported planar membranes as model systems (Connell and Smith, 2006). On the other hand, the main advantage of using fluorescence microscopy techniques in membrane studies is clear: the sensitivity and flexibility of a microscope with the addition of fluorescence spectroscopy allows for the collection of spatially resolved information at a submicrometer size scale, that is ~250-nm resolution (Bagatolli, 2006). This latter information connects membrane morphology with the dynamical and structural information obtained at the molecular level using fluorescence spectroscopy (such as lipid mobility, hydration, etc.).

The additional "visual" data obtained in these microscopy experiments using GUVs (Figure 22.3) or planar membranes have generated a new and very valuable piece of information that complements very well the "bulk" information obtained from the more classical approaches (Bernardino de la

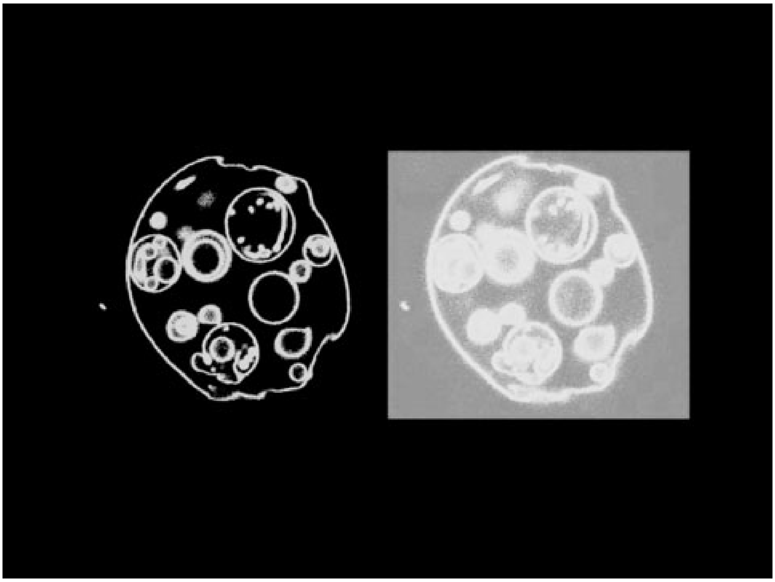

Fig. 22.3 " *Polifacético.*" Picture manipulation (giant lipid structures) (Bagatolli, 2006). Picture manipulations of lipid giant structures can be seen at the web page "science in your eyes" http://scienceinyoureyes.memphys.sdu.dk/index_en.php and in the author's personal page at http://www.memphys.sdu.dk/people/personal_pages/bagatolli/index1.php

Serna *et al.*, 2004; Dietrich *et al.*, 2001; Fidorra *et al.*, 2006; Nag *et al.*, 1998; Plasencia, Norlen and Bagatolli, 2007). This visual information can be used as an alternative to link the lateral structure of compositionally complex membranes (more than three components) with that observed in the compositionally simple cases (Bagatolli, 2006). Figure 22.4 represents an example of the overall information obtained combining differential scanning calorimetry and fluorescence microscopy techniques. In this particular case, complementary information is obtained from two different model systems (MLVs and GUVs) composed of pulmonary surfactant (Figure 22.4). This helps to establish correlations between this compositionally complex membrane and canonical (compositionally simpler) model lipid mixtures (DOPC:1, 2-Dioleoyl-sn-Glycero-3-phosphocholine /DPPC:1,2-Dipalmitoyl-sn-Glycero-3-phosphocholine/cholesterol in this case) (Bernardino de la Serna *et al.*, 2004), from which it is clear that lipid model systems have the potential to mimic not only molecular but also supramolecular levels of lipid membrane organization and dynamics.

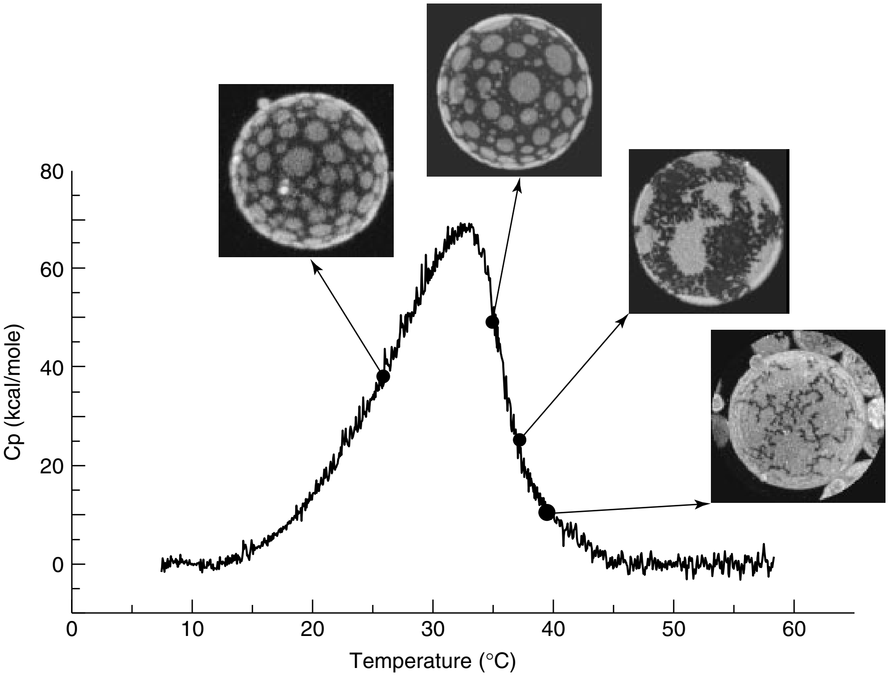

Fig. 22.4 Calorimetric profile of native pulmonary surfactant membranes (differential scanning calorimetry experiments) showing a low cooperative transition. The pictures show the actual lateral structure of the material at different temperatures (GUVs and fluorescence microscopy). The different areas in the microscopy pictures correspond to liquid ordered-(dark gray) and liquid disordered-like phases (light gray). Notice that dramatic changes in the structure of the material occur at temperatures slightly above physiological temperatures (37 °C). The figure shows the complementary information obtained from the different experimental techniques. For more details see (Bernardino de la Serna *et al.*, 2004).

22.4.2
Lipid–Protein Interactions

The vast bibliography connected with the study of lipid–protein interactions can be subdivided into studies that focus more on general effects of proteins in lipid membranes (and vice versa) and those related to a detailed description of specific cases involving particular proteins and lipids. Examples of the first category involve lipid-related enzymatic actions, membrane structural analyses (related for example to the influence of membrane proteins), hydrophobic matching, lateral pressure profile, membrane transport, membrane mechanics, and protein (peptide)-induced membrane permeability (Marsh, 2008; Mouritsen, 2005d).

Generally, the aforementioned experimental techniques (Section 22.4.1) are all used in lipid–protein interaction experiments (computer simulations, microscopy-related techniques, "bulk" techniques) providing important structurally and kinetically related information on different multimolecular systems. In these studies, the model systems are indeed based on proteoliposomes that are used directly or as the starting point to generate the model systems discussed above (i.e. planar membranes or GUVs). For example, the experiments performed with GUVs composed of pulmonary surfactant (presented in Figure 22.4) also explore the partition of surfactant hydrophobic proteins (SP-B and SP-C) when membrane heterogeneity is present in the native membrane (Bernardino de la Serna *et al.*, 2004). The partition or action of proteins (peptides) on model lipid mixtures were also explored visually, again providing a very good complement to "bulk" techniques (Ambroggio *et al.*, 2005a, 2005b; Kahya, 2006; Leidy *et al.*, 2004b; Sanchez *et al.*, 2002; Simonsen, Jensen, and Hansen, 2006; Thormann *et al.*, 2007) which also include mechanical measurements of peptide or protein interaction of membranes (Longo, Waring, and Hammer, 1997).

Additionally, the practical use of particular lipid–protein interactions in planar membrane systems as biosensors or for example, as "phantom cells" to study the interplay of specific "lock and key" relations between receptors and specific ligands (Sackmann, 1996) are a few of the interesting applications that emerge from basic studies related to protein–lipid interactions. Alternatively, the use of GUVs as bioreactors, encapsulating the cell-free expression system of bacteria and maintaining membrane protein synthesis for ~4 days (Noireaux and Libchaber, 2004) is one excellent model to study aspects of protein–lipid interactions. These studies try to mimic the process involved in first cellular life where the use of lipid models is a key element to develop proper experimental systems (Luisi, 2002; Monnard and Deamer, 2002).

22.4.3
Lipid–DNA Interactions

The interaction between nucleic acids and membranes has been extensively studied over the last decade due in large part to the great potential of these systems in gene delivery for gene therapy applications. One of the most important advantages for using liposomes in gene therapy is the lack of immunogenicity after *in vivo* administration, as compared to viral vectors (Smyth Templeton, 2002). One of the most important aspects of this liposome system is that is contains cationic lipids. Curiously, positively charged lipids are scarcely found as constitutive elements of natural membranes. The major problem with liposomes comprising natural lipids (neutral or negatively charged) is the low efficiency of encapsulating nucleic acids (e.g. plasmid DNA) (Sullivan, Gong, and Hughes, 2003). It is suggested that the presence of positive charges in the liposomes helps complexation with nucleic acids which are negatively charged (Sullivan, Gong, and Hughes, 2003).

This cationic lipid–DNA complex is called a *lipoplex* and was first reported during the late 1980s by Felgner *et al.* (1987). An effort has been directed toward designing different cationic lipids (Bajaj, Kondaiah, and Bhattacharya, 2008; Li and Szoka, 2007; Liu *et al.*, 2008) for generating cationic liposomes that can efficiently deliver nucleic acids. Generally, neutral lipids (called *lipid helpers*; e.g. 1,2-Dioleoyl-sn-Glycero-3-phosphoethanolamine (DOPE)) are also incorporated in these cationic liposomes to stabilize the liposome–DNA complex and modulate the particular physical properties of the liposome for optimum delivery (Li and Szoka, 2007; Sullivan, Gong and Hughes, 2003). This also includes the incorporation of polyethylene glycol (PEG)-lipids and lipid–polymer conjugates into these complexes to prolong liposome circulation (for *in vivo* delivery, called *stealth liposomes*), and to increase the efficiency of DNA release during delivery (Li and Szoka, 2007), respectively.

Several preparation methods have been proposed to generate nano-sized lipoplexes (Li and Szoka, 2007). These nanoparticles are designated according to the features of the generation methods: stabilized plasmid-lipid particle (SPLP), lipid-deoxyribonucleic acid particle (LDP), stable nucleic-acid-lipid particle (SNALP), nanolipoparticle (NLP), and pegylated immunoliposome (PIL). Methods to generate lipoplexes include many of the aforementioned liposome formation protocols such as detergent dialysis, ethanol injection and extrusion for example (Li and Szoka, 2007). *In vivo* delivery of these lipid–DNA complexes has extensively been tested and includes several routes such as direct injection (e.g. intratumoral), intravenous, intraperitoneal, mucosal (nasal, vaginal, rectal), transdermal, and subcutaneous to mention a few. The most promising delivery pathway seems to be the intravenous, and many investigators believe that this route can be efficient in the treatment of cancer, cardiovascular, and other inherited or acquired diseases (Smyth Templeton, 2002).

Finally, studies of lipid–DNA interaction have also been performed in GUVs. These studies focus on microinjection of giant DNA in the context of minimal life models (Nomura and Yoshikawa, 2000) and stability of cationic GUVs upon DNA injection (Angelova, Hristova, and Tsoneva, 1999).

22.5
Lateral Structure of Biological Membranes and Lessons from Model Membranes

The idea that lipids are simply randomly organized building blocks of membranes changed following the report of the coexistence of stable lipid domains in lipid bilayers three decades ago (Gebhardt, Gruler, and Sackmann, 1977; Shimshick and McConnell, 1973). However, the consequences of the nonrandom lateral organization of lipid membranes in the field of biological membranes, have not been acknowledged until recently, when the raft hypothesis was postulated (Brown and London, 1998; Edidin, 2003; Simons and Ikonen, 1997; Simons and Vaz, 2004). This hypothesis postulates that sphingomyelin/cholesterol rich areas are present in biological membranes as regions displaying a higher lateral order than the rest of the membrane (Simons and Vaz, 2004). Several membrane proteins are partitioned selectively into this area to promote signaling processes (Simons and Vaz, 2004). The main and serious drawback of this hypothesis is the way that these regions are identified, generally with the use of cold detergent extraction (Simons and Vaz, 2004). At present it is very clear (although several papers still are being published using this approach), that the addition of detergents at low temperatures *per se* generates membrane heterogeneity and this heterogeneity should thus not be associated with the presence of rafts (Lichtenberg, Goni, and Heerklotz, 2005; Sot *et al.*, 2006a). Additionally, insufficient attention is paid to the lipid composition and lipid–protein ratio of the studied membrane. In my opinion, the lateral heterogeneity of membranes is rather specific and related to compositional factors, rather than a general feature as is normally accepted. Still, and after 10 years of exhaustive investigation, the physical basis behind the lateral organization of biological membranes (including potential links with membrane function) remains obscure. For example, from the information obtained from membrane model lipid systems, the lateral heterogeneity of membranes can be rationalized simply as local (transient) compositional fluctuations or phase separation phenomena (Jacobson, Mouritsen, and Anderson, 2007). However, very little information is available about the occurrence of these two phenomena in real biological membranes. For instance, the presence of liquid ordered phases is repeatedly claimed in the literature but not always strictly demonstrated in many systems invoking rafts. This last observation points to the necessity of developing new experimental approaches in order to clarify the above-mentioned issues (Jacobson, Mouritsen, and Anderson, 2007). In particular, experimental information that allows correlation between the lateral structure of compositionally simple and complex membranes (as discussed above, Section 22.4.1) may help to identify the basis of membrane lateral heterogeneity in biologically relevant situations.

It is commonly accepted that raft size in biological membranes is of the order of tens to hundreds of nanometers, and thus not resolvable by conventional microscopy techniques. However, there are published examples of biological systems that display membrane domains with sizes of the order of micrometers; these data are not generally quoted in the raft literature, but are consistent with the lateral phase separation that is observed in some lipid model mixtures (Dietrich *et al.*, 2001; Kahya *et al.*, 2004; Veatch and Keller, 2005a). For example, transient micron-sized regions were reported Gaus *et al.* (2003) in living macrophages using the fluorescence probe 2-dimethylamino-6-lauroylnaphthalene (LAURDAN) and two-photon excitation fluorescence microscopy. This study demonstrated the presence of microscopically visible lateral phase separation in living cells, strongly supporting the notion that cholesterol had an effect on lateral organization in the membrane under study. Interestingly, this result is consistent with a report by Gousset *et al.* (2002) in which micron-sized domains were also observed in activated platelets. In the latter study, lipid mixtures with defined compositions (1-Palmitoyl-2-Oleoyl-sn-Glycero-3-phosphocholine (POPC), sphingomyelin, and cholesterol) based on the abundance of the major lipid components of the platelet membrane were used to mimic the lateral heterogeneity observed in this biological membrane (Gousset *et al.*, 2002; Leidy *et al.*, 2004a). This is similar to the case of pulmonary surfactant that contains high amounts of the saturated phospholipid DPPC, together with cholesterol, unsaturated phospholipids, and a low percentage of different membrane proteins, in which coexistence of liquid domains is observed (Figure 22.4) similar to that obtained in POPC/DPPC/Chol model systems (Bernardino de la Serna *et al.*, 2004). Perhaps the more exciting point of this work is that lateral phase separation is likely to be very relevant for the proper functioning of lung surfactant (Bernardino de la Serna *et al.*, 2004). The experimental approach described above can also be extended to other membranous systems, as was demonstrated by Ruan *et al.* (2004). In particular, the recent availability of GUVs containing the full composition of native biological membranes (Baumgart *et al.*, 2007; Montes *et al.*, 2007) is opening up exciting possibilities to proceed with this type of studies.

In the spite of the body of knowledge gained from model systems about biological membranes over the last decades, a call for new model systems is evident. Further developments into model membrane systems are expected in order to study the effect of other very important interactions, such as with the cytoskeleton (Miyata *et al.*, 2000) in order to study their influence on the actual lateral membrane organization.

22.6
Liposomes in Action

22.6.1
Liposomes and Delivery of Substances

Liposomes may satisfy very well the conditions that Paul Helrich, the father of modern medicinal chemistry, proposed for the magic bullet, that is, the perfect drug that targets diseased cells without affecting the healthy ones. Liposomes are water-containing capsules composed of biocompatible, nontoxic amphipatic materials (lipids) that may carry hydrophophilic substances in their interior and/or hydrophobic or amphipatic substances in the lipid bilayer. Moreover, they are soft and of variable size (the smallest can travel into the finest capillaries), and can be associated with specific chemical groups at the liposome surface that can act as homing devices targeting specific cells (Mouritsen, 2005e). In fact, the applications of liposomes for delivery of substances are beyond medicinal chemistry, although drug delivery for clinical applications is the most widely investigated area. These lipid entities are also utilized in the food industry and many cosmetic formulations (Lasic, 1998). Regarding the application of liposomes in medicine, there is an active effort trying to fight cancer by incorporating drugs into liposomes (Gabizon, Shmeeda, and Zalipsky, 2006). For instance, the abrupt change in permeability of liposomes during the gel–fluid phase transition was exploited by Needham *et al.* (2000) to release the anticancer drug doxorubicinin in combination with mild hyperthermia. The idea behind this experiment is that liposomes are sealed at physiological temperatures (while circulating) but upon heating (in the area where the tumor is situated) the liposome becomes leaky and releases the drug. The therapy was found to be significantly more effective than free drug or current liposome formulations (30 times or more) (Needham *et al.*, 2000). In the context of the Magic Bullet, the main disadvantage for this last application is that the tumor must be detected beforehand in order for the treatment to be efficient (in many cases this situation is not achievable). Another interesting strategy is the use of local tumor factors to induce local drug release from the liposome. For example, the fact that elevated amounts of phospholipases are present in tumors was used to degrade the liposomes containing drugs. It was further reported by Jorgensen and collaborators that lipidic nontoxic prodrugs can be circulated in stealth liposomes and be transformed into the active drug by the action of the abnormally high levels of phospholipases in the tumor, killing the malignant cells (Jorgensen, Davidson, and Mouritsen, 2002). These liposomes are called *LiPlasomes* and constitute a very promising approach to fight cancer (Mouritsen, 2005e). Several other clinical applications using liposomes include gene therapy, antibacterial and antifungal disorders, and vaccine entrapment (Banerjee, 2001; Goyal *et al.*, 2005; Gregoriadis *et al.*, 1999), showing the extraordinary versatility of these lipid model systems. Last but not least, liposomes are also utilized in the food science industry particularly to perform controlled delivery of proteins and enzymes, vitamins, and flavors as well as stabilization of food components against degradation (Taylor *et al.*, 2005).

22.7
Concluding Remarks

This chapter was intended to offer a broad overview of some of the many aspects where lipids are involved, particularly those related to membrane model systems and practical applications of lipid self-assembled structures. Lipids are fascinating molecules whose functions are not totally clear. Their capability to establish supramolecular (noncovalent) structures in aqueous media with very peculiar physical properties (related to soft materials) are exploited by nature to regulate many key functions of living systems. In the same context, practical use of lipid model systems have been realized with very promising applications that are surely still to come. In my opinion, rather than being dull molecules, lipids and their supramolecular structures are extraordinarily attractive and exciting biological elements. As can be concluded from this chapter, lipids and their structures are being examined by multiple disciplines with multiple approaches and objectives. One necessary point that can be drawn is that there is room for many more new ideas to help disentangle the many features of these important biological elements; some of them still hidden and waiting to be discovered.

Acknowledgments

This work was supported by funds from Forskningsrådet for Natur og Univers (FNU, Denmark) and the Danish National Research Foundation (which supports MEMPHYS-Center for Biomembrane Physics). The author would like to thank Robert Cantor for the critical reading of the manuscript and Signe Boe for her contribution of Figure 22.1.

25.1
Introduction: Aiming to Explain

Functioning of the human organism depends on regulatory processes that span an enormous range of spatial scales, from the nanometer scale of molecular conformation changes to the transmission of nerve signals over distances of the order of a meter. The fundamental elements of biochemical networks are nucleic acids (gene regulatory network), biomolecules (signaling networks), or small organic compounds (metabolic networks). The human genome may only have about 25 000 genes, but these genes code for more than 100 000 proteins, many of which serve more than one function. Although some are more likely than others, the number of conceivable interactions between all the human genes and their protein products is completely incomprehensive. At the cellular level, biomolecular signaling networks implement a new set of functions, including signal transduction, rhythm generation, and intercellular signaling. Tissues and organs, the next level of biological organization, again display completely new properties. Communication among the cells leads them to function in a coordinated manner that can be very different from the isolated behavior of the cells that constitute the tissue. Biological complexity cuts across time as well as space. At the molecular level, timescales of 10^{-9} seconds, characteristic of Brownian motion, are important, while aging processes and the development of diseases such as cancer and diabetes may involve timescales of the order of a human lifetime or 10^9 seconds.

Within this area of multidisciplinary research, systems biology and biosimulation are characterized by the following (Alon, 2007):

- Global rather than local analysis, or holistic rather than reductionistic perspective. This refers to the attempt of systems biology to capture and analyze many interconnected aspects of a biological system simultaneously. This is in contrast to the reductionistic approach where one or a few aspects are studied at a time.
- The simultaneous study of different levels of biological organization, often with the aim of describing how new properties and functions arise through the coordinated interaction of many units.
- The investigation of biological reaction cascades and feedback networks, including gene regulatory,

ISBN: 978-3-527-40702-6

protein interaction as well as signaling and metabolic networks.
- The explicit incorporation of time in order to capture and analyze dynamical behaviors and stimuli-response patterns of biological systems and processes;
- The use of concepts and tools from engineering and control theory to examine the role of particular feedback regulations and to determine the significance and stability of such regulations.
- The direct involvement of concepts from nonlinear dynamics and nonequilibrium thermodynamics to explain and describe observed temporal patterns, synchronization phenomena, and nonlinear wave propagation.
- The use of computational means to capture, model, and simulate biological processes and systems.

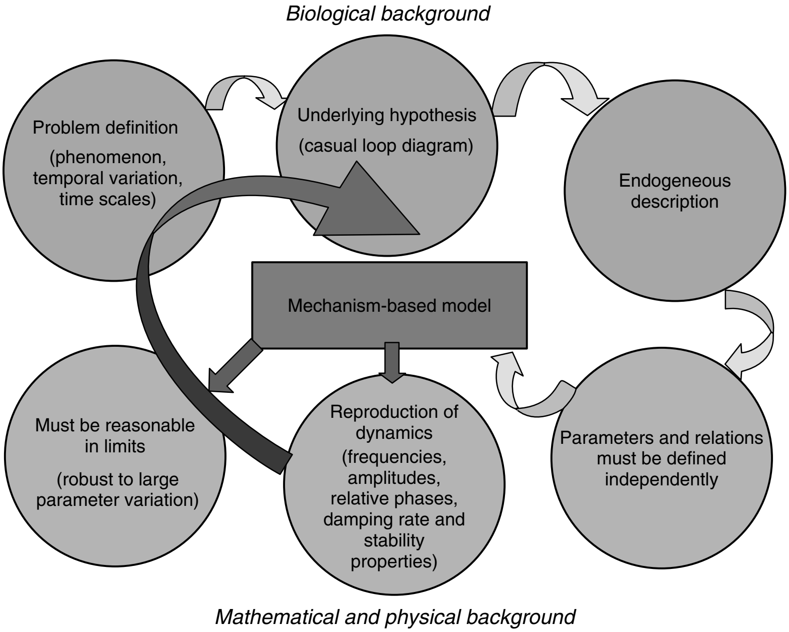
Biosimulation, as we define it, is the application of systems biology to solve concrete problems in the pharmaceutical industry or the health sector at large (Bertau, Mosekilde and Westerhoff, 2008). Successful work in this area clearly requires close collaboration between pharmacists, medical doctors, and modelers with a good understanding of feedback control, stability criteria, and nonlinear dynamics.

25.2
Approaches to a Systems Description

Computationally oriented biology involves two distinct approaches: (i) pattern recognition or data-mining that aims at extracting the hidden information from huge quantities of experimental data, in order to discover new phenomena, quantify their significance, and formulate hypotheses about the involved processes (Baldi and Brunak, 1998) and (ii) simulation-based analysis (or hypothesis-driven research) that aims at establishing a dynamic model that captures the key features of a system and is consistent with all available experimental information (Bertau, Mosekilde and Westerhoff, 2008).

Knowledge discovery and pattern recognition are used extensively within bioinformatics for such tasks as the prediction of exon-intron position and protein structure from a given sequence or the inference of gene regulatory networks from expression profiles (Baldi and Brunak, 1998; Kitano, 2001). These methods typically use predictions based on statistical discriminators that often involve sophisticated approaches (such as hidden Markov models) or other algorithms. In contrast, the simulation approach attempts to predict the dynamics of a system so that the validity of the underlying causal structures can be tested (Figure 25.1).

Although bioinformatics has long been used for genome analysis, protein structure determination, and drug-likelyhood predictions, simulation-based approaches have so far received less attention. This now appears to change. Convincing results obtained with the systems approach have lead to a significant boost in interest, and combined with substantial advances in software and computational power this has enabled the creation and analysis of reasonably realistic, yet intricate biological models, such as the full-heart model developed



Biological background
Problem definition
(phenomenon, temporal variation, time scales)
Underlying hypothesis
(casual loop diagram)
Endogeneous description
Mechanism-based model
Must be reasonable in limits
(robust to large parameter variation)
Reproduction of dynamics
(frequencies, amplitudes, relative phases, damping rate and stability properties)
Parameters and relations must be defined independently
Mathematical and physical background

Fig. 25.1 Illustration of some of the main aspects of mechanism-based modeling as outlined in the main text. Note in particular the important role of problem definition. It is through this process that we can separate different timescales and decide what is important and what is not.

by the universities in Oxford and Auckland (Hunter and Nielsen, 2005; Noble, 2002).

Mechanism-based modeling stems from engineering and other fields of science that have strong theoretical traditions. Computer simulation allows engineers to test the function of a new construction and compare it with other possible constructions long before the first prototype is made. The results are enormous savings in time and money. Direct application of the same approach to biomedical problems is primarily restricted by the overwhelming complexity of living systems. From physics, we have inherited the idea that one can separate processes and phenomena based on their temporal and spatial scales (Figure 25.1). This is obviously much more difficult for biological systems with their many and strongly coupled processes at overlapping time and space scales. Moreover, some of the most interesting problems are precisely to explain the coordination of processes that occur over separate timescales or to explain the properties of a tissue or the function of an organ in terms of the processes and interactions of the constituting cells or functional units.

A mechanism-based model is validated through its ability to generate behaviors with amplitudes, periodicities, phase relationships, response dynamics, damping characteristics, and stability properties in accordance with the experimentally observed dynamics (Mosekilde, Sosnovtseva and Holstein-Rathlou, 2005). At the end of the day, the model is validated by its ability to predict phenomena not previously experienced.

Two different paradigms can be recognized in the approach to model construction. In a bottom-up approach, the individual base elements of the system are first described in great detail. These elements are then linked together to form larger subsystems, which in turn are linked, sometimes in many levels, until a complete model is developed at the top level. This strategy often resembles a "seed" model, where the beginning is small, but the model eventually grows in both complexity and coverage.

The theory of complex systems suggests that the rules by which parts of a system interact may be more important than the functioning of the individual parts. In a top-down approach, an overview of the system is first formulated, specifying but not detailing relevant first-level subsystems. Each subsystem is then refined in yet greater detail, sometimes in many additional levels of subsystems, until the entire specification is reduced to basic elements. The top-down approach is most appropriate in a professional simulation environment that aims at developing a large, lasting, and flawless model. The bottom-up approach is generally used in research environments where the goal is to test hypotheses and gain understanding. A judicious combination of the two, sometimes referred to as a "middle-out" approach, may turn out to be the most effective solution in some situations (Bertau, Mosekilde and Westerhoff, 2008).

The purpose of this chapter is to illustrate the use of mechanism-based modeling and Biosimulation. We will first demonstrate some of the basic aspects of the model-building process by means of a strongly simplified description of the processes involved in regulation of the male sex hormone. Testosterone is found to be released in pulses with approximately 2-hour intervals, and we want to illustrate the possible role of feedback regulation in generating such ultradian oscillations. The second example provides a much more detailed description of the mechanisms by which the individual nephron of the kidney regulates its afferent blood flow to compensate, for instance, for variations in the arterial blood pressure. Additionally, this regulation is found to lead to self-sustained oscillatory dynamics.

25.3
Biological Rhythms and the Role of Feedback Regulation

Investigations performed during the last decades have revealed a great variety of rhythms of significance for the regulation and function of normal physiological systems. Hormonal secretion provides several illustrative examples with the release of luteinizing hormone (LH) (Smith, 1980), growth hormone (Bassett and Gluckman, 1986), and insulin (Polonsky *et al.*, 1988) displaying pronounced ultradian oscillations with 2- to 3-hour periods. The release of insulin also displays a faster rhythm with a period of 9–15 minutes (Bergsten and Hellman, 1993). These rapid oscillations are likely to be of significance for the metabolic control processes in the liver, and there are a number of examples to support the idea that rhythmic administration of a hormone can be more effective than constant administration at the same average rate. It is also known that disruption of certain biological rhythms can lead to a state of disease

(Glass and Mackey, 1988) while, in other cases, synchronization of ultradian release processes can cause abnormal biological conditions such as, for instance, hot flashes (Kronenberg *et al.*, 1984).

Many hormonal secretion processes also exhibit strong 24 hours, or circadian, components. This is true, for instance, for cortisol, antidiuretic hormone, and growth hormone. The secretion of growth hormone is markedly increased during the early periods of sleep, and the secretion of antidiuretic hormone also reflects the sleep–wake cycle. The stress hormone cortisol, on the other hand, shows a higher release rate during the last stages of sleep and in the early morning. This serves as a sort of wakeup call, and insulin secretion is similarly increased around the wakening hours in order to activate the body's muscular processes. The mechanisms underlying these oscillations can often be traced back to cyclical variations in the activity of the central nervous system (Hastings, Reddy and Maywood, 2003; Levi, 2001). At the same time, the circadian rhythm modulates the above-mentioned ultradian oscillations.

Feedback regulation is an important feature of all biological systems (Murray, 2002). If a process has an effect on other processes and these processes again have an effect on the first process, then a "circular" relationship or "loop" exists. This generally helps a system to maintain stability. Regulation of the blood–glucose concentration may serve as an example. Increasing concentration of glucose in the blood after a meal stimulates the pancreas to produce more insulin. The insulin is carried with the blood around in the body and diffuses through the capillary walls into the interstitial space, causing the cells to increase their uptake of glucose. This in turn reduces the amount of glucose in the blood, thus bringing the system back toward its initial state.

The insulin–glucose feedback is said to be a negative feedback in that an initial increase in blood–glucose concentration is counteracted by the release of insulin. Negative feedback regulations are generally considered as stabilizing to the system's dynamics. At the same time they reduce the significance of parameter variations, that is, two individuals can have different values for the cellular sensitivity to insulin and yet function more or less in the same way. Positive feedback, on the other hand, is destabilizing and leads to runaway phenomena. A typical example is the growth of cancer cells, which often occurs in a nearly exponential fashion. Positive feedback regulation is not common in physiological systems. However, one can find examples where a temporary positive feedback helps to stimulate a fast activation. Peptides in the stomach, for instance, stimulate the release of chloric acid that breaks down proteins and thereby generate even more peptides. Similarly, during the release of an ovum from the ovary there is a phase in which some of the sex hormones enter into a positive feedback.

However, a negative feedback regulation is stabilizing only as long as the feedback is fast enough, that is, the variables in the system must not change much before the change is registered and corrections applied to the variables. If there is a delay in the feedback, the regulation may become unstable, and the system will start to oscillate. This is the situation in both of the two examples we are going to discuss in this chapter. The presence of a delay is also the mechanism through which many other rhythmic phenomena arise in biological systems. We say that the system has undergone a Hopf bifurcation in which the original equilibrium point has become unstable (an unstable focus), and a self-sustained oscillation (or limit cycle) has taken over the role as the stationary solution (Thompson and Stewart, 1986).

25.4
Instabilities and Far-From-Equilibrium Conditions

From a physical point of view, the rhythmic phenomena are related to the fact that biological systems are maintained under far-from-equilibrium conditions through a continuous dissipation of energy (Nicolis and Prigogine, 1977). However, nonequilibrium conditions can give rise to even more complicated behaviors. Chaotic dynamics, for instance, can arise either as a regular rhythmic process is destabilized and develops through a cascade of period-doubling bifurcations (Feigenbaum, 1980), by torus destruction in connection with the interaction of two or more rhythms with incommensurate periods (Afraimovich and Shilnikov, 1991), or via different types of intermittency (Bergé, Pomeau and Vidal, 1984).

Deterministic chaos is characterized by the facts that (i) the trajectory never repeats itself, but continues to find new ways to go and (ii) the dynamics is sensitive to small changes in the initial conditions (Bergé, Pomeau and Vidal, 1984). Deterministic chaos may resemble random noise, and it can be difficult to distinguish the two. However, while a noisy system always responds in the same way to an external perturbation, the response of a chaotic system can vary significantly over the phases of its trajectory. In relation, for instance, to the medical treatment of a patient, this implies that while in a linear system the effect of a drug will always be the same, the precise timing of the administration may be significant for a rhythmic (or chaotic system). During certain phases of the oscillation, even a major dose may have little effect while a smaller dose may be highly effective (or perhaps even toxic) during other phases. Attempts to take advantage of this phenomenon are made, for instance, in experiments with chronotherapy of cancer and other diseases (Mormont and Levi, 2003).

Synchronization is another universal phenomenon in nonlinear dynamical systems (Pikovsky, Rosenblum and Kurths, 2001), a phenomena by which two (or more) rhythmic processes tend to adjust their dynamics relative to one another so as to attain a state where they are completely entrained or, alternatively, a state in which there is a rational relation between their periods. The synchronization of our circadian rhythm to the local time and the aforementioned role of hormonal entrainment in the generation of hot flashes are typical examples. It is also well known that the beating of the heart may synchronize with the respiration, typically with 1:3 or 1:4 relations between the two periods. By forcing an oscillating system with an external periodic signal and detecting the various synchronization regions, one can obtain information about the nonlinearities at play in the system. An example of this type of work is the investigation by Sturis *et al.*(1995) of how the endogenous insulin secretion can synchronize with an externally forced periodic glucose infusion.

The significance of nonlinear dynamic phenomena seems to be even more pronounced at the cellular level. Coupling between the cells takes place via a variety of different mechanisms, including the short-range diffusive exchange of ions and small molecules through gap junction and the response of the individual cell to variations in the intercellular Ca^{2+}-concentration produced by the bursting activity of adjacent cells (Chay, 1997). Hence, one can observe synchronization of the bursting activity between neighboring cells as well as waves of cytoplasmic calcium propagating across larger groups of pancreatic cells (Gylfe, Grapengiesser and Hellman, 1991). The above-mentioned rapid oscillations in the secretion of insulin may be associated with a modulation of the bursting activity of the individual cells that arises from such intercellular interactions.

Synchronization of cellular activity is known from many other types of tissue, and transitions between different types of synchronization and between smaller and larger clusters of synchronized units may represent an important component in the overall regulation of a physiological system. In their inactive state, smooth muscle cells, for instance, are found to exhibit incoherent waves of cytoplasmic Ca^{2+} produced by an instability associated with calcium-induced calcium release. When activated, however, the cells synchronize in a regular oscillatory pattern (Peng *et al.*, 2001). On the other hand, several cases are known where a similar transition is related to the development of a state of disease. It has long been recognized, for instance, that the onset of Parkinsonian tremor is associated with a synchronization of the firing activity for a group of cells in the brain (Tass, 2001).

25.5
Luteinizing Hormone

In this section, we will use a simple example of hormonal regulation to illustrate the basic principles of systems biology and feedback control. By means of a system dynamics flow diagram (Morecroft and Sterman, 1994), we build a model of the control of the production of the most important male sex hormone, testosterone, and we use this model to discuss some of the aspects of the physiological mechanisms that cause the pulsatile behavior of the system.

System dynamics (Morecroft and Sterman, 1994) makes use of flow diagrams to illustrate the structure of interacting mechanisms that produces the dynamic phenomena we observe in managerial and economic systems. However, the same approach is applicable to biomedical systems. Flow diagrams can be considered as a language following a set of principles that must be used, in order to avoid ambiguous interpretations. In system dynamics, a system is described by a set of state variables, rates of change of these variables, auxiliary variables, exogenous variables and delays, each represented by a specific symbol in the flow diagrams.

25.5.1
Model of the Pulsatile Release of Luteinizing Hormone

In humans (and other mammals), the secretion of sex hormones, testosterone for males, and estradiol and progesterone for females, are controlled by the production of LH, which again is controlled by the production of a releasing hormone called gonadotropin-releasing hormone (GnRH). In turn, the production of GnRH appears to be controlled by the amount of circulating testosterone (Yen, Jaffe and Barbieri, 1999).

A particular interesting aspect of the gonadotropin-releasing hormone–luteinizing hormone–testosterone (GnRH–LH–T) system is that the hormone secretion takes the form of pulses. A GnRH-pulse is followed a few minutes later by an LH pulse, while it takes approximately 30 minutes for LH to stimulate the production of T to its maximum. A pulsatile release of GnRH is crucial for the system to function normally. It was shown by Knobil (1980) that constant replacement of GnRH production fails to establish normal LH concentrations. On the other hand, various diseases, such as hypothalamic amenorrhea and hypogonadotropic hypogonadism, have been treated successfully with pulses of GnRH (Leyendecker and Wildt, 1985).

System dynamics makes a clear distinction between amounts and concentrations with respect to their function in the models. The amounts of different hormones in their respective distribution volumes and their rates of change through production, degradation, transfer to other distribution volumes, and so on, are the elements of the material conservation equations for the system, and they constitute the backbone of the models. Concentrations do not satisfy similar conservation equations, and use of concentrations as basic variables can often cause confusion in models with different or time-varying distribution volumes. On the other hand, biological effects are controlled by concentrations, and the concentration of various hormones, therefore, enter the model's causal relations. Concentrations are, of course, calculated from the corresponding amounts by division by the relevant distribution volume. In this way, causal relations will always start at a level (or state) variable and end at a rate variable.

When the concentration of GnRH increases, it stimulates an increasing production of LH and, as long as the production of LH exceeds its rate of degradation in the organism, this leads to increasing amounts of LH. This first step in constructing a model is described by the flow diagram in Figure 25.2, where the valves indicate the rates

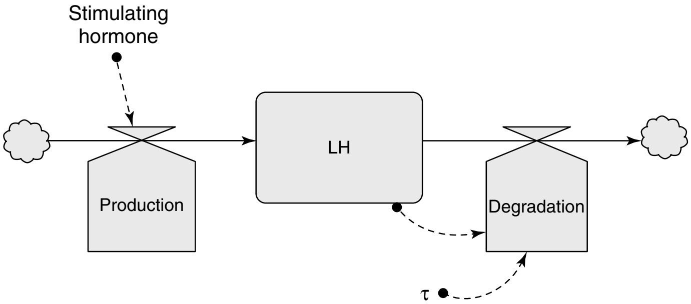


Fig. 25.2 Flow diagram of a production/degradation process. LH denotes the amount of hormone, and the arrows indicate flow directions with valves to illustrate that the flow is controlled by other variables or constants.

of production and decay. Rate-related parameters, for instance hormone lifetimes, are indicated by dashed curves pointing into the valve. The boxes represent material accumulations of a given hormone. The solid straight arrows indicate flow direction and dashed curves indicate causal dependences. The rate of degradation depends both on the lifetime and on the amount of hormone, since the more hormone is present the more hormone will degrade per unit time. The rate of hormone production depends on the current concentration of the stimulating hormone through a nonlinear relationship, which typically follows an S-shaped function. This implies that very little LH is produced at low concentrations of the stimulating hormone. Then follows a range of concentrations where the production of LH increases rapidly before it finally levels off at a maximum production rate.

In a similar way, stimulation of testosterone production in dependence of LH follows an S-shaped curve, such that increasing amount of LH stimulates an increasing production of T. An increase in T, on the other hand, is assumed to have an inhibitory effect on the production of GnRH. The system thus constitutes a negative feedback loop. A flow diagram of the described hormonal feedback system is shown in Figure 25.3. Note, that material flows are expressed by fully drawn straight arrows and causal dependences (i.e. physical and chemical laws or biological control mechanisms) are described by dashed curves. Dashed curves always emanate from a state variable and end at a rate.

These three interhormonal dependences have been experimentally studied (Veldhuis, 1991) and to a first approximation they follow the S-shaped curves shown in Figure 25.4.

From a biological point of view the most appropriate functional relationship for the S-shaped curves are Hill functions of the form

$$S(x) = \frac{Vx^n}{K^n + x^n} \tag{1}$$

where V is a saturation production rate, K is a constant that determines the position of the equilibrium point, and n a parameter that determines the slope of S at the equilibrium concentration x_0, which is also the turning point of the curve. Note, that the value of n is negative for $S_R(T)$.

The corresponding equations for the production of the three hormones are

$$\begin{aligned} \frac{dR}{dt} &= S_R(T) - R/\tau_R \\ \frac{dL}{dt} &= S_L(R) - L/\tau_L \\ \frac{dT}{dt} &= S_T(L) - T/\tau_T \end{aligned} \tag{2}$$

where the parameters τ_R, τ_L, and τ_T are hormonal lifetimes and $S(\cdot)$ are appropriately scaled S-shaped functions. Variables and indices R, L, and T refers to GnRH, LH, and T. The equilibrium point of this system is found by requiring the flows to vanish, whereby we find the equilibrium point

$$\begin{aligned} R_0 &= K_R \\ L_0 &= K_L \\ T_0 &= K_T \end{aligned} \tag{3}$$

The stability of the equilibrium is found by evaluating of the Jacobian matrix J at

the equilibrium point

$$J = \begin{pmatrix} -1/\tau_R & 0 & n_R V_R/(4K_R) \\ n_L V_L/(4K_L) & -1/\tau_L & 0 \\ 0 & n_T V_T/(4K_T) & -1/\tau_T \end{pmatrix} \tag{4}$$

and taking the determinant to obtain the characteristic polynomium. For a third-order system, this polynomium is also of third order $P(\lambda) = \lambda^3 + A\lambda^2 + B\lambda + C$, and for the present model the coefficients are

$$\begin{aligned} A &= \frac{1}{\tau_R} + \frac{1}{\tau_L} + \frac{1}{\tau_T} \\ B &= \frac{1}{\tau_R\tau_L} + \frac{1}{\tau_L\tau_T} + \frac{1}{\tau_T\tau_R} \\ C &= \frac{1}{\tau_R\tau_L\tau_T} - \frac{n_R n_L n_T}{64}\frac{V_L V_R V_T}{K_L K_R K_T} \end{aligned} \tag{5}$$

The Routh–Hurwitz stability criterion (Meirovitch, 1970) for a third-order system states that the coefficients of the characteristic polynomium must fulfill the conditions

$$A > 0,\ B > 0,\ C > 0 \text{ and } AB - C > 0 \tag{6}$$

The first three conditions are clearly fulfilled for all physical relevant values of the delays constants τ_R, τ_L, and τ_T. A more complete analysis of the system identifies the critical point, where $AB - C = 0$, as a Hopf bifurcation. The last equality can be explicitly written as

$$\frac{(\tau_T + \tau_L)(\tau_T + \tau_R)(\tau_R + \tau_L)}{(\tau_R\tau_L\tau_T)^2} > \frac{n_L n_R n_T}{64}\frac{V_L V_R V_T}{K_L K_R K_T}. \tag{7}$$

With experimentally measured lifetimes of $\tau_R = 3$ minutes, $\tau_L = 40$ minutes, and $\tau_T = 40$ minutes (Zolman, 1985) and equilibrium values of $R_0 = 5$ pg ml^{-1}, $L_0 = 25$ pg ml^{-1}, and $T_0 = 12$ pg ml^{-1} (Smith, 1980) we obtain the saturation values $V_R = 3.3$ pg (ml s) $^{-1}$, $V_L = 3.75$ pg (ml s) $^{-1}$, and $V_T = 1.2$ pg (ml s) $^{-1}$. The equilibrium point is stable for Hill exponents fulfilling the condition

$$|n_R n_L n_T| > 41.5 \tag{8}$$

By means of this inequality, we can decide the values of the slopes such that the hormonal release over time shows an oscillating behavior. It is assumed that the response of L to R is fast since the hypothalamus and pituitary gland is located relative closely to the hypothalamus in the brain, while the response of T to L is slow since L must be transported over a significant distance to the testes where the production of T takes place. Realistic values would be $n_R = -6$, $n_L = 6$, and $n_T = 6$. The time evolution of the simulated hormone concentration with these values is shown in Figure 25.5. Clearly, the behavior is oscillatory, however, the period is only approximately 50 minutes, which is more than a factor 2 too fast as compared with experimental findings. The parameters that most directly control the period are the lifetimes of the hormones. However, since the values have been measured experimentally there appears only to be one solution to the problem, namely to amend the production rate functions. The parameter V also influences the period, but this parameter has a strong influence on the amplitudes, and it is therefore not possible by varying this parameter to obtain both the amplitudes and the period correct at the same time. An alternative solution could be to examine the effect of delays that may

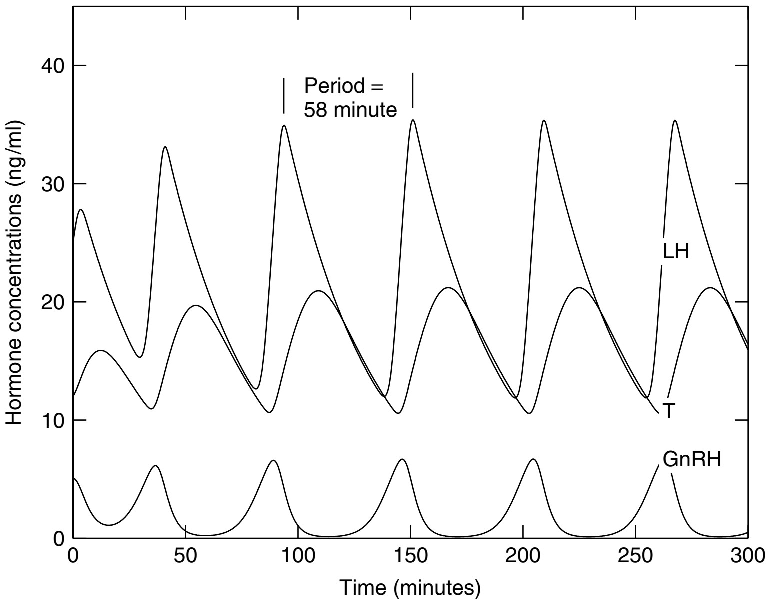

Fig. 25.5 Simulated time evolution for releasing hormone (GnRH), luteinizing hormone (LH), and testosterone (T). The parameters used in this simulation yield a period of 58 minutes between the bursts of LH secretion. In reality the period is closer to 2 hours.

be involved in the hormonal production. The presence of such delays could at one and the same time provide a longer period and a more pulsatile dynamics.

One possible way of increasing the period is to insert an extra delay in order to account for the time it takes to activate the cells to change their hormonal production.

A significant set of functions may fit the experimentally observed S-shaped hormone production response. However, few of them have a physiological interpretation in terms of biochemical processes. For instance, the logistic function, $V/(1+\exp\{K(x-x_0)\})$, could fit the relationship between hormone concentration and production rate quite well. But it is not possible to relate the exponential function to the mechanisms that control the receptor dynamics. Hill functions, on the other hand, are accepted as a mechanistic model of receptor dynamics, since there is some correspondence between the parameters of the function with the chemical constants of the biological process.

Finally, we note that there might also be an inhibitory interaction between LH and GnRH, such that high concentrations of LH may slow down the production of GnRH, whereby the full development of a cycle is retarded.

25.6
Nephron Pressure and Flow Regulation

As an example of a more detailed application of the mechanism-based approach we will consider a model that combines a description of nephron blood flow regulation with a description of the reabsorption of water and salts in the loop of Henle. A model of nephron autoregulation has been presented previously (Leyssac and Holstein-Rathlou, 1989). The purpose of that model was to examine the processes underlying the observed rhythmic and chaotic variations in pressures and flows observed for normotensive and hypertensive rats, respectively. Reabsorption of water and salts in the loop of Henle has been described in Sakai *et al.* (1986), but in a spatially extended model that is too complicated to allow detailed bifurcation analysis. The idea of the present study is to combine the two processes into a lumped model that retains sufficient simplicity to permit us to perform a more detailed bifurcation analysis.

25.6.1

Physiological Background

By regulating the excretion of salts, water, and metabolic end products, the kidneys play an important role in maintaining a suitable environment for the cells of the body. In particular, the kidneys control the plasma osmolality, the proportion of various blood solutes, the extracellular fluid volume, and the blood pressure. To protect their own function and secure a relatively constant blood flow, the kidneys also dispose of mechanisms that can compensate for variations in arterial blood pressure. It has long been recognized that this ability partly rests with controls in the individual nephron primarily the so-called tubuloglomerular feedback (TGF) (Moore, 1984). This is a negative feedback that regulates the diameter of the afferent arteriole, and hence the incoming blood flow, in dependence of the chloride or sodium concentration of pre-urine leaving the loop of Henle.

The nephron may be considered as the functional unit of the kidney. The human kidney contains about 1 million nephrons, while the rat kidney contains some 30 000 nephrons. However, the structural features, the main physiological processes, and the qualitative behavior appear to be similar to those of the human kidney. The differences are almost completely associated with the parameter values. The model we present here is a model of a single nephron initially formulated by Jensen *et al.* (1986) and later studied in greater detail by Barfred, Mosekilde and Holstein-Rathlou (1996). The intricacies of the nephron–nephron coupling, discussed in a number of recent studies (Postnov *et al.*, 2001), are neglected here.

Figure 25.6 shows the tubular structure of a nephron. The inset to the nephron from the body's vascular system is the afferent arteriole, originating from sequential branching of arteries. The blood enters the glomerulus, which extracts water and various substance, except blood cells and proteins. The extracted fluid flows further into the convoluted proximal tubulus. Approximately 70% of the glomerular filtrate is reabsorbed from the proximal tubule into the capillary network and collected by the outgoing venous system. This isosmotic process is controlled completely by a hydrostatic pressure gradient. The residual fraction becomes important for the feedback mechanism later in the filtration. The remaining 30% of the filtrate enters the thin descending loop of Henle where additionally 15% of the water is reabsorbed giving rise to an increased concentration of NaCl as the limb is impermeable to salts. On passing the

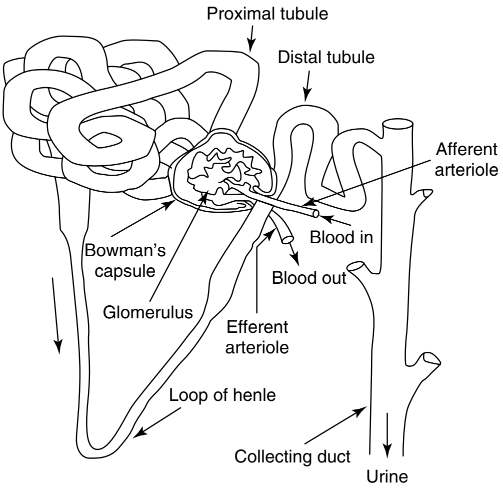

Fig. 25.6 Sketch of a nephron with its main components. The incoming blood from the afferent arteriole is filtered in the glomerulus. In the proximal tubulus a large part of the filtered fluid is reabsorbed and further reabsorption of water takes place in the descending limb of Henle, while salt reabsorption takes place in the ascending limb. At the point of contact between the distal tubulus and the glomerulus macula densa cells measure the salt concentration and send transmitters to the smooth muscle cells, which cause a constriction of the afferent arteriole at large salt concentrations.

ascending limb the filtrate is again diluted as Na^+ and Cl^- are reabsorbed, while the limb is largely impermeable to water. At the end of Henle's loop, the tubulus comes into cellular contact with the afferent arteriole of the same nephron. At these points special cells, the so-called macula densa (MD) cells, sense the Na^+ concentration. If the rate of glomerular filtration, due for instance to an elevated arterial blood pressure, is too high, the active reabsorption of NaCl is not complete, and the salt concentration at the MD is too high. The MD cells then produce transmitter agents that cause the flow resistance of the afferent arteriole to increase by radial contraction, hence lowering the glomerular pressure and thereby reducing the filtration rate. A second mechanism that contributes to the autoregulation is the myogenic response of the afferent (and possibly the efferent) arteriole. Basically it is an active response that counteracts increases in arteriolar pressure by increasing constriction/tension of the vessel caused by the smooth muscle cells in the arteriolar wall. The detailed chemical mechanics of the myogenic response are still not fully understood. In the present model a semiempirical macrophysiological description of this process is adopted.

Although most tissues in the organism dispose of a myogenic mechanism that allows them to control the incoming blood flow in relation to their metabolic and other needs, the TGF mechanism is specific to the nephrons of the kidney. This mechanism is seen as a way for the nephrons to protect their own function against variations in the arterial pressure. The causal loop diagram in Figure 25.7 illustrates the main elements of the TGF mechanism as described earlier. The feedback is negative in that increasing arterial pressures lead to higher filtration rates that result in higher NaCl concentrations at the MD leading to arteriolar contraction and reduced filtration rates. However, the feedback involves a delay of approximately 12 seconds associated with the time it takes the filtrate to flow through the loop of Henle.

Early experiments by Leyssac and Baumbach (1983) and by Holstein-Rathlou and Leyssac (1986) demonstrated

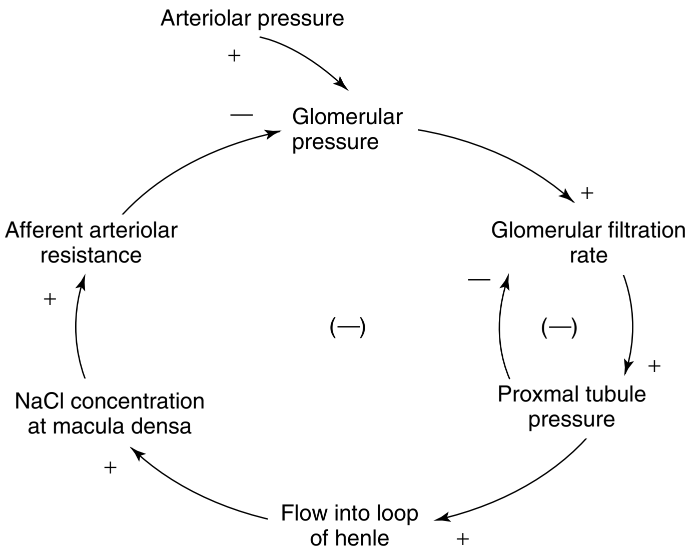

Fig. 25.7 Causal loops for TGF. Minus indicates a negative influence and plus indicates a positive influence in the arrow direction. Altogether the loop represents a negative feedback. However, because of the delay associated primarily with the fluid flow through the loop of Henle, and because of a relatively high gain factor the regulation tends to become unstable and produce self-sustained oscillatory dynamics.

that the feedback regulation could become unstable and generate self-sustained oscillations in the proximal intratubular pressure with characteristic periods of 30–40 seconds. Although for normotensive rats the oscillations had the typical appearance of a limit cycle, highly irregular oscillations were found for spontaneously hypertensive rats (SHRs). Oscillations were observed for 50–80% of the investigated nephrons. For nonoscillatory nephrons, self-sustained oscillations could be elicited by microperfusion with artificial tubular fluid, that is, by artificially increasing the rate of flow through the loop of Henle. Subsequently, it has been observed that similar irregular oscillations can develop for normal rats, if the arterial pressure is increased by ligating the blood supply to the other kidney.

25.7
Single Nephron Model

In this section we construct the model step by step and collect all the subsystems into one coherent description of the tubular and arteriolar system. We have already presented the fluid flow through the nephron. In the following the total function of the nephron is grouped into specific submodels representing glomerular filtration rate (GFR), flow through the loop of Henle, the arteriolar resistance, and a macroscopic model of the smooth muscle cells in the afferent arteriole. This description will follow the structure of the corresponding flow diagram as depicted in Figure 25.8.

In Figure 25.8 (left), we follow the flow of blood from the arterial system through the afferent arteriole, the glomerular capillaries, and the efferent arteriole to the venous system. The two arterioles are represented by their flow resistances of which the efferent resistance is assumed to be constant. The afferent flow resistance varies as part of the pressure and flow regulation. The blood flow through the glomerular capillaries is determined by the pressure difference between the arterial and venous sides and the two flow resistances. The glomerular capillaries are represented as a (small) compliant blood volume. The GFR depends on the difference between the glomerular pressure and the proximal tubular pressure accounting, of course, for the difference in protein

Fig. 25.8 Flow diagram for the single nephron model. There are four main flows in the diagram: (i) The blood flow through the glomerular capillaries, (ii) the glomerular filtration, (iii) the flow through the loop of Henle, and (iv) the rate of change of arterial radius and its second-order rate of change. The feedback on the arterial blood flow is realized by the dependence of the arterial resistance on the arterial response to pressure. Description of the processes that take place in the loop of Henle is here reduced to a single flow rate and a delay. A lumped representation is shown in greater detail in Figure 25.9.

osmotic pressure across the capillary wall. It is assumed that the blood reaches pressure equilibrium before it leaves the glomerular capillaries. The equation for the proximal pressure is derived from the in- and outflows to the tubule

$$\frac{dP_t}{dt} = (F_{filt} - F_{reab} - F_H)\,\frac{1}{C_t} \tag{9}$$

where F_{filt} denotes the flow of filtrated fluid, F_{reab} the reabsorption, F_H the flow from the proximal tubule in the loop of Henle, and C_t is the proximal tubular compliance. The large reabsorption of both water and salt in this early tubule is represented in the flow diagram by the arrow pointing from the tubular fluid volume to the venous system. The salt concentration remains approximately constant in the proximal tubule as the tubular wall is equally permeable to water and salts.

The loop of Henle is modeled as a tube divided into a number of consecutive compartments, each with their specific physiological properties. In order to account for the mechanistic differences between water and salt reabsorption, the amounts of water and salt must be considered separately as shown in Figure 25.9, where the upper part of the chain is the water volumes and flows between the compartments and the lower part represents the amounts of salt in the various compartments along the chain. Again, we model this system by the mass conservation of the filtrate for each compartment and apply our knowledge about the physical properties of the tube and fluid, which for instance are the compliance and resistance of the tube and the transit times between the compartments. The flow rate of water entering the first compartment of the thin descending limb from the proximal tubules is the inset to the flow diagram. This flow rate depends on the compliance and resistance of this compartment and on a delay time representing the time needed for the fluid to move from the proximal tubulus to the first compartment. Reabsorption of water into the capillary system takes place through the interstitium, however this process is considered to fall outside the boundaries of the model, since it only has little influence on the TGF mechanism. Reabsorption of water is osmotic and therefore depends on the concentration difference across the tubular wall and on the permeability of the wall.

In Figure 25.9 the lumped loop model is depicted with two descending compartments, each with reabsorption of water. The ascending limb is represented by three compartments. While there is no reabsorption of water in the ascending limb, reabsorption of salt takes place according to usual Michaelis–Menten kinetics. However, there is also an osmotic backleak of salt from the interstitium into the tubule. This backleak has only little influence on the dynamics of the model when operated in the normal working regime. However, if the flow through the loop becomes very small, the reabsorption of water will decrease, while the active salt reabsorption remains almost unchanged, giving rise to an increased salt gradient across the ascending limb. The backleak mechanism seeks to re-establish the normal salt balance by allowing paracellular diffusion.

At the end of the loop in Figure 25.9 the amounts of both water and salt yields a salt concentration which passes the MD cells at the intersect of the distal and juxtaglomerular apparatus, permitting

the arteriolar model to respond to the NaCl concentration through the TGF transfer function.

Several experiments have shown that the radius of arterioles may perform spontaneous or self-sustained oscillations (Funk *et al.*, 1983; Aalkjær and Nilsson, 2005), that is, independent of the pressure variation due to TGF. According to Poiseuille's law, the resistance of the arteriole is inversely proportional to the fourth power its radius. Hence, constrictions of the arteriolar radius cause a reduction in blood flow into the glomerulus. This mechanism is modeled by a second-order differential equation of the form

$$\frac{d^2r}{dt^2} + d\frac{dr}{dt} = \omega^2 \frac{P_{\mathrm{trans}}}{P_0} \tag{10}$$

where r is the normalized radius, d is a damping coefficient, P_{trans} the transmural pressure, ω a characteristic angular frequency, and P_0 a normalization pressure. The transmural pressure is a quite complicated variable to describe for this system. It is expressed as the difference between the average pressure P_{av} of the fluid in the vessel and the equilibrium pressure P_{eq} for which the arteriole is in equilibrium with this pressure at its present radius and muscular tone.

$$P_{\mathrm{trans}} = P_{\mathrm{av}} - P_{\mathrm{eq}} \tag{11}$$

On top of the elastic reaction of the arteriolar wall P_{el}, activation of the smooth muscle cells in this wall gives rise to an additional contribution ψP_{ac} to the equilibrium pressure that the wall can sustain at a given radius, that is,

$$P_{\mathrm{eq}} = P_{\mathrm{el}} + \psi[\mathrm{NaCl}]P_{\mathrm{ac}} \tag{12}$$

Here, $\psi[\mathrm{NaCl}]$ is the strength by which the active constriction takes place. If the salt concentration at the MD, [NaCl] is low, then ψ is also low, thus reducing the contraction of the afferent arteriole and, hence, increases the glomerular filtration. The dynamics of the active contribution, better known as the myogenic response, is discussed in the following paragraphs. The corresponding equations are represented in the flow diagram of Figure 25.8 by two rates labeled d^2r/dt^2 and dr/dt with corresponding state variables.

The myogenic response is a process that is best understood on the cellular level. It is often observed that models on some space and time level need to include processes on other levels. We have already seen one example of this: the Michaelis–Menten transport of salt in the ascending loop of Henle. This process can also be described on the chemical level, but the thermodynamic average causes a macroscopic relationship to be a sufficient description of the process. By using a similar approach, Feldberg and Colding-Jorgensen (1995) have derived a macroscopic relationship between the constriction of arterioles and blood pressure, which includes the effect of the smooth muscle cells. The model is based on the assumption of nonlinear elastic stress–strain relationship and a linear relationship between the muscle tone and the active stress component.

The degree to which the afferent arterial resistance is changed due to an increased glomerular filtration is called the TGF transfer function (or loop gain). As mentioned earlier the values returned by the function is called the muscular tone. Actually, the TGF transfer function can be defined as a function of any variable along the loop of Henle; however, it is mechanistically most obvious to let it be a function of salt concentration at the site of the MD cells, since this is the terminal of the tubular system relevant for the autoregulation mechanism. The function is an S-shaped function with lower and upper limits, turning point and a slope at the turning point which can be determined by microperfusion experiments (Leyssac and Holstein-Rathlou, 1989). Especially the slope and upper limit of the function show characteristic differences between normotensive and hypertensive rats.

25.8
Simulation and Analysis

The model we have discussed in the preceding sections can be formulated mathematically as a set of ordinary differential equations. For the model with two descending and three ascending compartments of the loop of Henle 18 equations are required. Two of the equations describe the oscillations of the arterial wall and one describes the pressure in the proximal tubulus. Each compartment, whether descending or ascending, is described by three equations representing fluid volume, amount of salt, and the delay of the fluid transport between the compartments. Computer simulations of the equations show a great variety in the dynamical behavior.

The TGF transfer function has been experimentally recorded by inserting a plug of wax in the middle of the proximal tubulus of the rat, so that the flow in the tubular system is blocked. On the other side of the wax plug a micropipette is inserted and artificial tubular fluid is infused at a constant rate. With time, the system approaches a steady state and the pressure in the early proximal tubule is recorded.

With our mathematical model simulations of the microperfusion experiments can be made by setting the GFR to zero and setting the flow into the loop of Henle to a constant rate, representing the externally forced infusion.

Complete bifurcation analyses are hard to perform on systems of the size of the present model. However, biological systems are often infected by noise making it very difficult, if not impossible, to experimentally observe, for instance, a second period-doubling bifurcation after the first period doubling has occurred. For the present model observations of a steady state, a cycle of double period and chaos allows us to limit the analysis to bifurcations leading to these dynamical behaviors. Figure 25.10 shows a bifurcation analysis with the total delay time T and strength α of the TGF transfer function as the parameter. For small α values the system is in equilibrium with no time-dependent variations. As α is increased, the equilibrium point becomes unstable in a Hopf bifurcation, and a limit cycle is born. As it is clear from the figure, a further increase of α may give rise to a cycle of double period followed by a period-doubling cascade leading to chaotic dynamics. The existence of all four types of behaviors is important for the validity of the model. But additional validation is required in order to claim that the model and parameters used are correct. As mentioned earlier, the period of the oscillations has been measured to be in the range 30–40 seconds. The period of the simulated oscillations depends mainly on the delay time T. For delays in the range 9–13 seconds, the

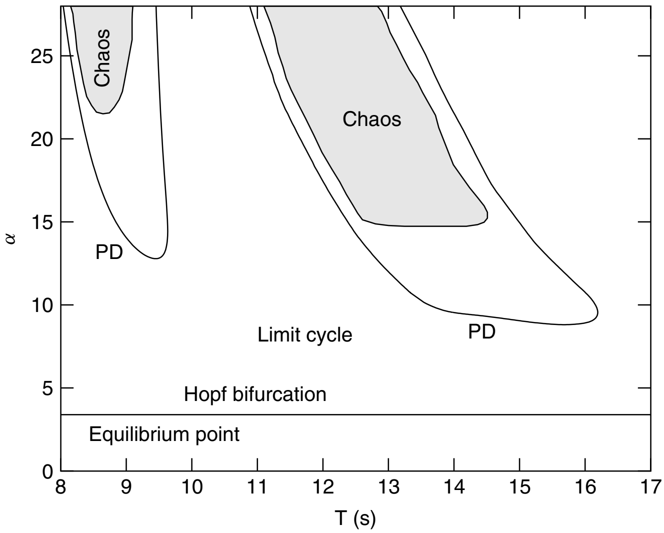

Fig. 25.10 Two-parameter bifurcation diagram for the extended nephron model showing the Hopf bifurcation at $\alpha \approx 4$, two tongues delineated by period-doubling bifurcations, and the regions dominated by chaotic dynamics.

period resembles those measured experimentally, a range that partly covers the region with all of the four types of dynamics (Figure 25.10). The scan through the diagram at constant $T = 12.5$ seconds is displayed. Figure 25.11 shows the dynamical behavior in more detail. The period doubling at $\alpha = 14$ is followed by a cascade of period-doubling transitions leading to deterministic chaos. At larger α a reverse period-doubling cascade terminates the chaotic region, a new cascade is initiated, and new regions with chaos appear. At $\alpha = 12.5$ and $\alpha = 17$, the periodic and chaotic attractors are shown (A and B) in Figure 25.11.

Fast oscillations of the proximal pressure and arterial wall arise as a consequence of the pulsatile contractions of the smooth muscle cells when the arterial pressure is high. For the period-1 cycle shown in Figure 25.11 the fast oscillations are clearly visible, as the orbit makes five fast cycles for each of the slow TGF-mediated oscillations. The number of fast oscillations per cycle of the slow oscillations depends on the parameters of the model, and as we increase the value of α (or T) we move from a region with 5:1 dynamics into a region with six oscillations for each slow oscillation.

The idea of creating a lumped model of the loop of Henle is to model the salt concentration along the loop. With the chosen number of compartments, we obtain average concentrations within each compartment, and parameters specific to the tubules wall anatomy are either integrated over the compartment length if originally specified as a value per length or divided by the number of compartments if originally given as an effective parameter for the whole loop.

The temporal evolution of the tubular pressures along the loop is shown in Figure 25.12 for a delay of $T = 12.5$

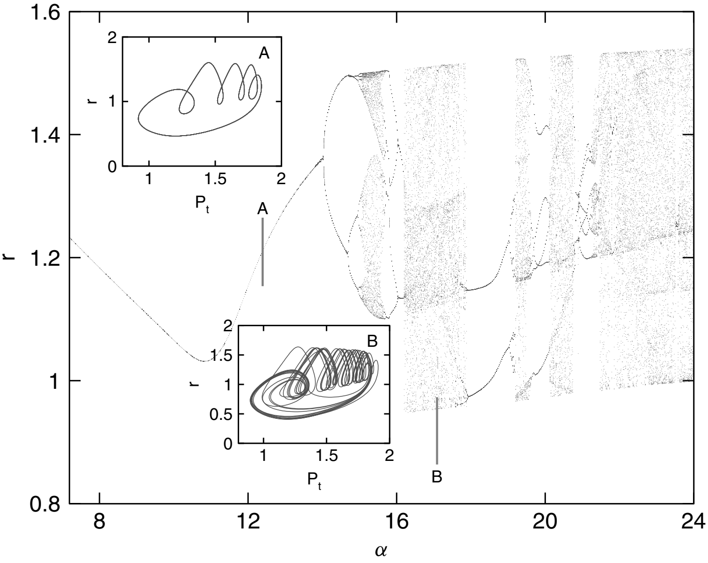

Fig. 25.11 Diagram showing the bifurcations and solutions as the TGF gain α is varied while the delay is kept constant at $T = 12.5$ seconds. At low α, the solution is oscillatory with a period of 38 seconds. As α increases, a period doubling takes place at $\alpha \approx 14$. Thereafter a cascade of period doublings leads to chaotic dynamics interrupted by periodic windows.

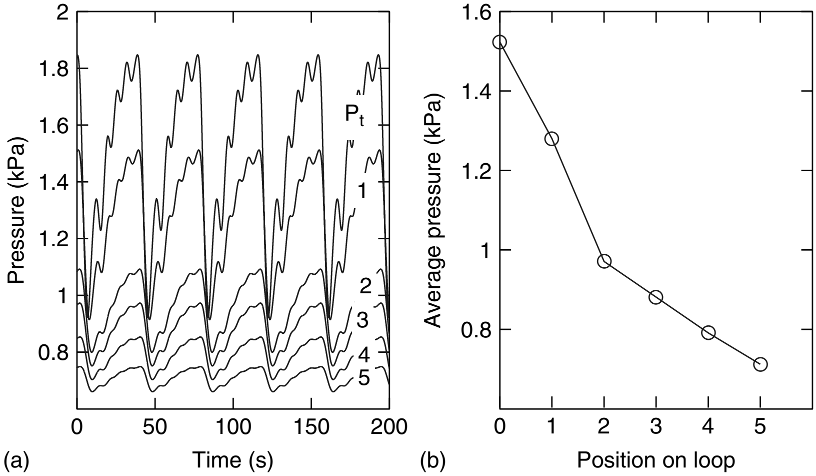

Fig. 25.12 Tubular pressures. (a) Time evolution of the pressures along the loop beginning with the proximal pressure (labeled P_t). Oscillations have a period of approximately 38 seconds. Note, how the amplitude of the oscillations is increasingly damped. (b) Time average of the pressures along the loop.

seconds and a TGF feedback gain of $\alpha = 10$. For this value of the total delay the period is 38 seconds, and we also see that there is a phase shift of 11.5 seconds between the proximal pressure and the distal NaCl concentration. The phase shift depends on the tubular compliances along the loop, since a highly compliant tubular segment can accommodate fluid at high pressure and release it as the pressure decreases. Also the decreasing amplitude of the pressure is accounted for by the relative large compliance in connection with the flow resistance.

Variation in time of the salt concentration along the loop is shown in Figure 25.13. In the proximal tubule, the concentration is defined constant equal to 150 mM in accordance with experimental knowledge. With appropriate absorption rates, the concentration increases in the descending limb to 350 mM in the second compartment corresponding to the bend of the loop. In the subsequent compartments that represent the ascending limb the Michaelis–Menten reabsorption of NaCl accounts for the decrease toward a concentration of 30 mM at the end of the loop.

Both this phase shift and the presence of period doubling and chaos depend on the compliance of the loop of Henle. For increasing compliance the phase shift increases and the period doubling and chaotic regions appear at larger values of α. Compliances measured in vitro (Sakai *et al.*, 1986) have indicated that the Henle compliance may be approximately 20 times larger than the proximal compliance. However, simulations with these larger values completely destroy the picture of the above findings. This seems to demonstrate that, when living tissue is taken out of its natural environment, the properties may change drastically. One should also not forget that the tubular system of the nephron is surrounded

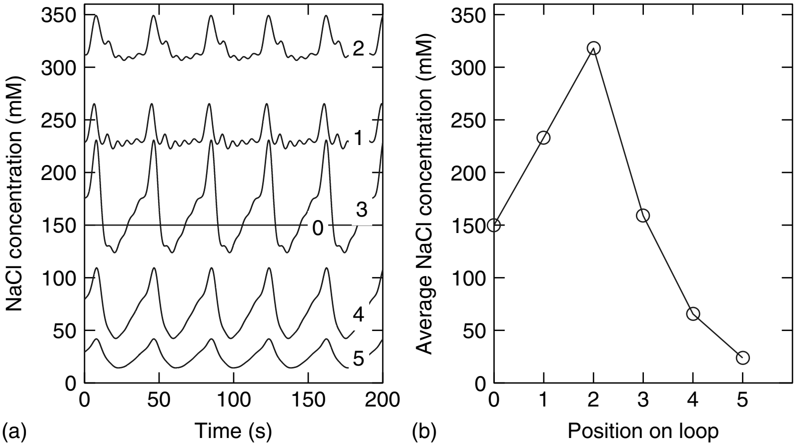

Fig. 25.13 NaCl concentrations. (a) The time evolution of the NaCl concentration along the loop with the proximal concentration defined constant equal to 150 mM. Along the loop a phase shift evolves and at the distal tubulus the phase shift between the proximal pressure and the distal salt concentration is 11.5 seconds. (b) Time average of the concentrations. Clearly, the concentration increases in the descending limb (0–2) and decreases in the ascending limb (3–5).

by the tissue of the interstitium, which may have a large effect of the dynamical properties.

In this chapter, we have described a lumped model of a single nephron in the kidney. This model combines a description of the interacting myogenic and TGF-mediated mechanisms of nephron autoregulation with a description of the reabsorption of water and salts in the loop of Henle. The following are the key features of nephron autoregulation we have aimed to reproduce:

- Four types of qualitative different dynamical behaviors: equilibrium state, oscillatory, oscillatory with double period, and chaotic.
- A phase shift in the oscillation between the proximal pressure and distal NaCl concentration of 10–15 seconds.
- TGF transfer functions obtained by microperfusion experiments on normo- and hypertensive rats.
- Increasing NaCl concentration along the descending limb and decreasing NaCl concentration along the ascending limb of Henle's loop.
- Slow and fast oscillations of periods 30–40 seconds and 5–6 seconds, respectively, the fast oscillations being caused by the model for the afferent arteriole.

Other aspects of the nephronic system are described in our recent publications (Sosnovtseva *et al.*, 2003; Sosnovtseva *et al.*, 2007).

25.9
The Promise of Systems Biology

Understanding the complex dynamic phenomena of the living world is one of the main scientific challenges of the coming decades. The way to acquire such understanding must necessarily involve a more direct and effective integration of experimental and computational research. Hypothesis-driven or mechanism-based modeling is an approach in which the physiological, pathological, and pharmacological processes of relevance to a given problem are represented as directly as possible. This approach allows us to (i) test whether assumed hypotheses are consistent with observed behavior, (ii) examine the sensitivity of a system to parameter variation, (iii) learn about processes not directly amenable to experimentation, and (iv) predict system behavior under conditions not previously experienced. By virtue of the direct physiological interpretation of the involved parameters, mechanism-based modeling provides a tool for translation between species and interpolation among groups. This implies, for instance, that the pharmaceutical industry to a certain extent can predict human responses to a new drug from animal experiments by replacing the physiological parameters with parameters relevant to man.

Systems biology is a scientific approach that seeks to understand how all the individual components of a biological system interact in time and space to determine the functioning of the system. This involves description of

- the structure of a biological system; that is, the significant physiological components and their structural relationships at the appropriate spatial scale;
- the dynamical behavior of the system under different conditions and external perturbations;

- the mechanisms that control the states and behavior of the system;
- the causes of system changes in connection with various diseases and the methods by which such changes can be counteracted or compensated.

A model of a biological system can only be expected to reproduce experimentally observed features, if the mechanisms responsible for these features are implemented in the model. Therefore, a model can never be expected to reproduce all experimental findings. However, a model is usually build with the intension to model specific phenomena and behaviors. If some of these key features fail to be produced, a revision of the model is required.

26.1
Introduction

A superconductor is crudely speaking a material that can conduct electric currents without losses, that is, without dissipation. Fritz London (1900–1954), one of the greatest contributors to the understanding of superconductivity, in his book on superfluids (London, 1950) speculates about the possible occurrence of the phenomenon in biological macromolecules. After the quantum mechanical foundation for understanding superconductivity had been developed (Bardeen, Cooper, and Schrieffer, 1957), William Little pursued the idea and argued that properly designed organic polymers might show superconductivity at ambient temperatures (Little, 1964). These ideas spurred an enormous interest in developing and studying electrically conducting organic materials, and beginning in 1980 (Jerome *et al.*, 1980) several families of organic superconductors were synthetized and investigated in great detail. Typically they superconduct at very low temperatures (most often below 10 K), and to date there is no convincing evidence for superconductivity in biological materials, except for reports on the so-called proximity induced superconductivity in DNA (Kasumov *et al.*, 2001). However, the activity in the area has continued partly because of lack of a deep understanding of the inorganic high-temperature superconductors, which work at moderate but still low temperatures (around 100 K). It is hoped that the high flexibility of organic chemistry would lead to the fulfillment of the old promise of a room-temperature superconductor.

It is the aim of this short review to describe the main advances in the field of organic superconductivity. We start out with a brief introduction to the phenomenon of superconductivity, on the macroscopic as well as the microscopic scale. For a more detailed treatment, the reader is referred to standard textbooks on the subject (see, for example, Tinkham, 1996). Next, an overview of the development of the various groups of superconducting materials is presented. In the main sections, we deal with the basic properties of the superconducting organics including their rich behavior in terms of ordered phases, which to a large extent is due to the reduced effective dimensionality encountered. We do not include materials with π-bound carbon sheets like C-60 compounds and carbon nanotubes, which are hardly more organic

ISBN: 978-3-527-40702-6

than graphene and graphite. Finally, we conclude with an outlook for future directions in the field.

26.2
What is Superconductivity?

26.2.1
Basic Properties

Superconductivity is associated with an ordered phase of the conduction electrons in a material. The main signatures for an ideal superconductor are the absence of electrical resistance (up to a certain critical current) and the Meissner effect (Meissner and Ochsenfeld, 1933) – the expulsion of magnetic fields (up to a critical magnetic field strength, H_C). If the critical values are exceeded, the material reverts to the normal resistive state. As with other ordered phases, an increasing temperature favors a high entropy, that is, a disordered state. For a superconductor in zero field, this is reflected by the fact that there is a continuous phase transition at a well-defined transition temperature, T_C, above which superconductivity is lost. These basic properties are illustrated in Figure 26.1.

26.2.2
Thermodynamics, Condensation, and Order Parameter

Experimentally, it is found that the specific heat is exponentially activated below T_C. After a drop at T_C, it follows the behavior of a normal metal. This suggested a two-fluid model (Gorter and Casimir, 1934), where starting at T_C a macroscopic fraction of the conduction electrons condenses into a collective state of zero resistance and zero entropy. The fraction increases with decreasing temperature and approaches unity at $T << T_C$. At a given temperature, statistical equilibrium between condensate and normal (“evaporated”) electrons exists. This approach requires a condensation or binding energy for the condensate electrons. It also allows the establishment of a relation between the critical magnetic field and the difference in free energy between the normal fluid and the superconducting fluid. The phenomenological approach to superconductivity culminated with the

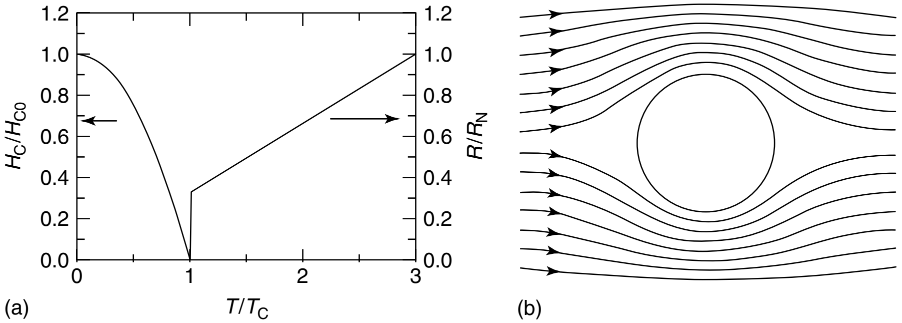

Fig. 26.1 (a) Behavior of resistance and critical magnetic field as function of temperature for ideal model superconductor. The values are normalized to the room-temperature and zero temperature values, respectively. (b) Schematic picture of the Meissner state. The magnetic field lines are expelled from the superconductor.

two equations of Fritz London and Heinz London, which account for the fascinating electrodynamics of superconductors (London and London, 1935). The first of the London equations simply states the absence of friction when the superfluid accelerates in an electric field, while the second is the integral with respect to time of Faraday's law of induction with the additional postulate that the constant of integration is zero. The London equations fully account for the Meissner effect, since they show that a superconductor in the ideal Meissner state carries a superconducting sheet current in the surface, which gives rise to a magnetic field contribution in the interior, which exactly cancels the applied field. The current density is not infinite; thus, the magnetic field has a penetration depth, λ, which from the London equations is

$$\lambda = \sqrt{\frac{m}{\mu_0 n_s e^2}} \tag{1}$$

In this expression, m and e are the electron mass and charge, respectively, $\mu_0 = 4\pi \times 10^{-7}$ Vs Am^{-1} is the vacuum permeability, while n_s is the density of electrons in the superfluid. Typical densities give numbers for the penetration depth in the range 50–200 nm well below T_C (i.e. corresponding to many interatomic distances). As the condensate density decreases with increasing temperature, the field penetrates deeper, and finally $\lambda \to \infty$ as the critical temperature is approached.

Systems undergoing continuous phase transitions are often described in terms of an order parameter. In a ferromagnet, for example, the order parameter is the magnetization vector, a three-dimensional quantity. For superconductors, it is found that a two-dimensional order parameter suffices. It is conveniently given in complex form as

$$\Psi(\mathbf{r}) = \sqrt{n_s(\mathbf{r})}\exp[i\theta(\mathbf{r})] \tag{2}$$

hence with an amplitude equal to the square root of the superfluid density, but with a variable phase, θ. For simplicity, we have assumed stationary conditions, but allowed for spatial variations. It turns out that the order parameter may be interpreted as a genuine macroscopic quantum mechanical wave function describing the superfluid and it is fully consistent with the London equations.

The order parameter is the basis of development of a much more detailed phenomenological theory for superconductivity (Ginzburg and Landau, 1950). The free energy may be expanded as a power series in the order parameter, and minimization leads to the two Ginzburg–Landau equations that integrate the thermodynamic, the quantum mechanical, as well as the electrodynamical properties of superconductors. Although in principle they are only valid near T_C, they work fine in a much wider range and constitute a standard tool for physicists working in this area. They still do not explain the physical origin of the condensation energy, which, however, as noted above is simply related to the critical magnetic field.

Before turning to the microscopic theory, let us introduce another fundamental length, the coherence length ξ (Pippard, 1953), which is the shortest distance over which the magnitude of the order parameter can vary significantly (e.g. dropping from a finite level to zero). A simple expression for ξ may be obtained from the uncertainty principle. Pippard assumed that only electrons with energies in a range kT_C around the chemical potential (the Fermi energy) participate in the ordering, which appears at T_C. The corresponding momentum range is kT_C/v_F, v_F being the velocity of the electrons at the Fermi level. Hence, we may estimate

$$\xi \cong \frac{\hbar}{\Delta p} = \frac{\hbar v_F}{kT_C} \tag{3}$$

The coherence length is quite material dependent. For example, in aluminum ($T_C = 1.2$ K) it is 1600 nm, while in the commonly used niobium ($T_C = 9$ K) it is 40 nm. The relation reflects an important issue, namely, that the higher the T_C, the shorter the coherence length will be. In the high-temperature superconductors, it is of order of a few nanometers. Thus, much of the robustness of superconductivity, which is due to the fact that the order parameter cannot be destroyed over short length scales, is lost as the transition temperature and the condensation energy increase. The coherence length may also be derived from the Ginzburg–Landau equations, showing that it diverges when approaching T_C. To some extent, the expression in Eq. (3) may be understood as the low-temperature extrapolation of the Ginzburg–Landau result.

26.2.3
Microscopic Understanding

After many unsuccessful attempts, the now universally accepted Bardeen–Cooper–Schrieffer (BCS) theory of superconductivity appeared in 1957 (Bardeen, Cooper, and Schrieffer, 1957). At that time it was realized that a weak indirect attraction between electrons in a metal existed. One electron traveling through a particular spot will start polarizing the surrounding ionic lattice. Because of the heavy ions, this is a fairly slow process; hence, when another electron passes by a little later, it will experience a lowering of its energy (Fröhlich, 1950). Because the two electrons in question need not be close in distance, the effective attraction may dominate over the direct Coulomb repulsion.

No matter what is the origin of the net attraction, it makes the Fermi-sea of normal electrons unstable to the formation of Cooper pairs (Cooper, 1956). In the simplest picture, Cooper pairs combine electrons of opposite momentum and spin. We will skip the details, which rest on a combination of a net attraction and on the restrictions on occupancy of the electronic states imposed by the Pauli principle. It is important to understand that a Cooper pair does not consist of two particular bound electrons. Rather there is a rapid dynamical exchange of electrons near the Fermi level. As might be expected, there is a close relation between the size of a Cooper pair and the superconducting coherence length (Eq. (3)).

The BCS theory proposes a ground state wave function where all electrons are combined into Cooper pairs, but with occupancies depending on the wave vector. The elementary excitations are combined electron- and holelike with a threshold energy (half the energy gap, $E_G = 2\Delta$) and statistical mechanics provided in the simplest weak coupling limit the following expressions for the energy gap and transition temperature:

$$E_G = 2\Delta = 3.5kT_C \cong 4\hbar\omega_0 \times \exp\left[-\frac{1}{N(0)V}\right] \tag{4}$$

The relation between the energy gap, which in a sense represents the binding energy of a Cooper pair, and the transition temperature is a general consequence of the BCS theory being a mean-field theory, where all fluctuations are neglected. The expression on the right-hand side contains the prefactor ω_0, which is the characteristic frequency of the mediator of the interaction (in the model discussed, it is the lattice vibration (phonon) frequency), and in the exponential function we find the density-of-states at the Fermi level for the metal, $N(0)$, and the effective attractive interaction at play near the Fermi surface, V. This already provides some guidelines for optimizing T_C: pick a mediator of high frequency, select a metal with a high density-of-states, and make sure that the effective interaction is as high as possible.

The BCS theory in many ways explains the behavior of all known superconductors. For example, the energy gap for excitations prevents scattering of the conduction electrons, and hence predicts the zero resistance state. It is possible to show that the Ginzburg–Landau equations follow from the BCS theory; so all the electrodynamics, and so on, is accounted for.

A particularly important experimental observation concerns the Cooper pair formation. A consequence of the electrodynamics of superconductors is that magnetic flux through a superconducting ring is quantized in units of h/q_s, where q_s is the charge of the "particle" making up the superfluid. The flux quantization is fairly easy to measure, and in all known cases it has been found that $q_s = 2e$, consistent with the existence of pairing.

Although the BCS theory seems to be highly successful in providing a general framework for understanding superconductivity, it is very nonspecific regarding the detailed microscopic mechanism responsible for the attraction between electrons. The mediators of the attraction could well be magnetic or purely electronic with quite different energy scales. The traditional test for the involvement of the ionic lattice has been studying the isotope effect. The vibration frequency, ω_0, in Eq. (4) scales with the inverse of the square root of the ionic mass. Thus, on substituting isotopes, the transition temperature should change in a systematic matter, which has been confirmed in many of the traditional low-temperature superconductors. However, in strong coupling, high-temperature superconductors the effect may be masked, because a simple expression such as Eq. (4) no longer applies, and several subtle side effects of substitution have also been observed.

Exotic mediators may also result in more complex Cooper pair formation. The traditional Cooper pair has a spherically symmetric *s*-wave orbit and a spin singlet (antiparallel spin directions). In interpreting results for several unconventional superconductors, *p*-wave and *d*-wave symmetries as well as triplet states (parallel spins) are encountered. They are all compatible with the BCS theory, but it is quite difficult to distinguish them experimentally. However, there is rather strong evidence for substantial *d*-wave pairing in the ceramic high-temperature superconductors.

26.2.4
Molecular Superconductivity and Little's Proposal

One signature of superconductivity is the occurrence of persistent currents in closed rings. They can be set up by cooling a ring in a magnetic field to below T_C and then switching off the field. The enclosed flux will be trapped. Now it is generated by a persistent current in the ring, which will continue to run until the ring is heated to above T_C. Likewise, a superconducting ring being exposed to a magnetic field will set up a persistent current to keep flux out of the ring. Sometimes it has been argued that the diamagnetic screening current in, for example, benzene molecules, which is also persistent in the sense that it continues to run as long as a magnetic field is present, may be explained by the fact that the π-electrons in the ring have superconductivity. However, this is a simple quantum mechanical consequence of having switched on a magnetic field combined with the unavailability of other non-current-carrying states in the same energy range, and is also known to occur in nanoscale normal metal ring structures. In a truly superconducting ring, the decay of a persistent current is due to the vanishing probability that all the Cooper pairs change their momentum state simultaneously, which is necessary to retain the BCS state. Thus the physics involved is quite different, and we will only by superconductivity understand superfluid formation involving a condensation energy.

There are several approaches to maximize T_C in designing a material. The basic idea of Little (1964) was to use long unsaturated polyene chains and attach, on the side of the chains, small and highly polarizable molecules, for example, dye molecules. The mediators of attraction between conduction electrons on the chains would then be essentially electronic transitions (excitons) on the dye molecules with a frequency, ω_0, in the optical range, which is obviously much higher than any lattice frequency. Also, if the chemistry allowed the dye molecules to be placed close enough to the chains, the interaction V would be appreciable. According to Little's sensible theoretical estimates, transition temperatures of order 1000 K should be achievable! Unfortunately, there is no firm evidence for this kind of excitonic superconductivity to date, but the proposal has had – and to some extent still has – a strong impact on research activities.

26.2.5
History of Superconducting Materials

For natural reasons there has been a lot of interest in the development of superconducting transition temperatures. Figure 26.2 shows a few of the more well known advances in terms of T_C versus year of discovery. It all started in 1911, when Kamerlingh-Onnes shortly after liquefying helium for the first time found mercury (Hg) to be superconducting below 4.2 K. Several other elemental metals (squares) were found to exhibit superconductivity, including niobium (Nb) with $T_C = 9.5$ K. These are the so-called type I superconductors, where theoretically $\xi > \sqrt{2}\lambda$. Type I superconductors have typically a rather low T_C and display the simple magnetic field behavior outlined above with a Meissner state below a single critical magnetic field, which is also rather low, typically 0.01–0.2 T. This ruins their applications in high-current, high-magnetic-field applications.

Indeed, in materials where ξ is smaller than λ, a different behavior is found. This is related to the fact that the interface energy at a boundary between the normal metal (N) and the superconductor

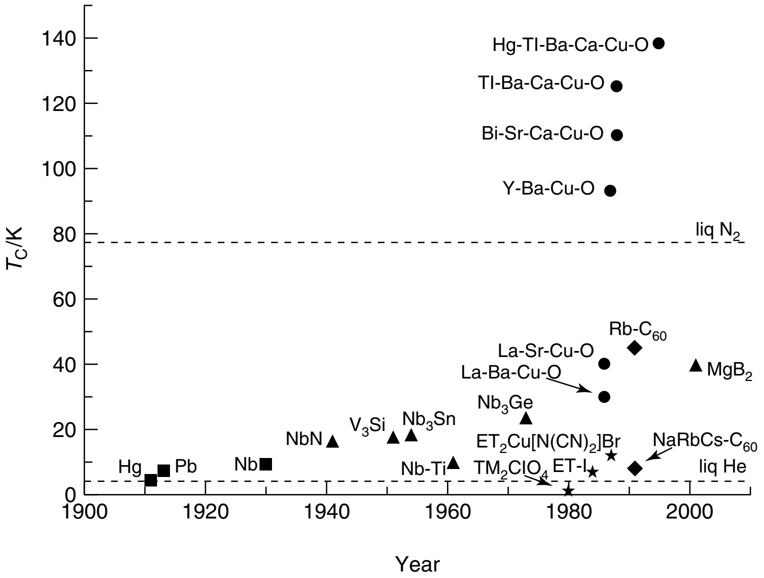

Fig. 26.2 Schematic picture of the historical development of superconductors: transition temperatures versus year of discovery. Squares: elemental superconductors. Black triangles: alloys and intermetallics. Stars: organic conductors. Circles: ceramic copper-oxide (high temperature) superconductors. Diamonds: doped C-60 (Bucky balls). The temperatures of liquid helium and liquid nitrogen are indicated with dashed lines [Sources: http://superconductors.org/ and Butch *et al.*, 2008.].

(S) goes from being positive to being negative. When ξ is small, the boundary layer is almost completely superconducting; hence, condensation energy is gained, while the magnetic field is allowed to penetrate to a greater depth. The fact is that it becomes advantageous for the material to have as much NS-interface as possible. For very low fields (below a lower critical field, H_{C1}), the Meissner state with complete flux expulsion is still found. Above H_{C1}, magnetic flux lines quantized in units of $\Phi_0 = h/2e$ start penetrating the bulk of the material. These entities are called *vortices*, since they have a normal core of approximate radius ξ, while the surrounding superconductor is shielded from the penetrating magnetic flux by a current vortex of approximate radius λ. For increasing magnetic field, the vortex density increases, and only when the normal cores start to overlap, superconductivity breaks down. Thus this happens at an upper critical field, which may be estimated as $H_{C2} = \Phi_0/\mu_0 \pi \xi^2$. In the so-called mixed state between the two critical fields, the vortices tend to arrange themselves in a two-dimensional triangular lattice (Abrikosov, 1957). In such type II superconductors, the upper critical field is often tens of tesla and in the high-temperature superconductors it may be hundreds of tesla.

In Figure 26.2 the triangles give examples of traditional type II superconductors, often alloys like Nb–Ti ($T_C = 9.5$ K) or intermetallic compounds like Nb_3Sn

($T_C = 18$ K). These two materials are the ones most often used for high-current, high-field applications (e.g. for magnetic field coils in magnetic resonance imaging MRI systems), but they still require expensive cooling most often in the form of liquid helium.

In 1973, Nb_3Ge with $T_C = 23$ K was found and for a number of years this remained the record. Then in the 1980s, the organic superconductors appeared on the scene (the stars in Figure 26.2), but the transition temperatures have so far remained modest. The discovery of the ceramic high-temperature superconductors in 1986 revitalized the field and the magic temperature of liquid nitrogen was soon exceeded. Currently a lot of research and development focuses on the technological development of these materials. Finally Figure 26.2 gives examples of doped fullerenes (C-60) as well as the recently discovered MgB_2 ($T_C = 39$ K).

26.3
Organic Superconductors

26.3.1
Organic Conductors

The flexibility of organic chemistry encouraged researchers to work with semiconducting organic materials as early as in the 1950s. For a review of this early work, see, for example, Gutmann and Lyons (1967). Excluding polymers, which so far have not shown bulk superconductivity, the overwhelming majority of organic conductors are based on charge transfer complexes. Usually organic molecules are closed shelled, so when incorporated in a crystal the electronic structure will consist of completely filled and completely empty energy bands. Thus insulators result. A charge transfer complex contains an electron donor (low ionization potential) and an electron acceptor (high electron affinity). The charge transfer provides unpaired charge carriers. Donor or acceptor or both may be organic, or one of them inorganic (for a thorough review, see Jerome and Schulz, 1982; see also Batail, 2004).

To achieve delocalization of charge carriers in the crystal, often π-bound rather planar molecules are used. A number of representative molecules are shown in Figure 26.3. The π-orbitals are oriented perpendicular to the molecular plane and tend to favor the formation of molecular stacks with significant intermolecular contacts within the stacks.

The first really excellent organic metal TTF–TCNQ (tetrathiafulvalene–tetracyanoquinodimethane (Ferraris *et al.*, 1973)) has a schematic crystal structure as shown in Figure 26.4.

The energy balance within the crystal results in an average transfer of 0.55–0.59 electron from TTF to TCNQ. Both donor and acceptor stacks form narrow one-electron bands of widths of order 0.6 eV (Jacobsen, 1988). Such a small bandwidth suggests that short-range electron–electron repulsion is important. The room-temperature conductivity along the stacks is of the order of 60,000 $(\Omega m)^{-1}$, about thousand times smaller than that of copper. Perpendicular to the stacks it is 100–1000 times lower. In an early work, the stacking axis conductivity was found to increase rapidly with decreasing temperature, reaching a maximum of order 500 times the room-temperature value near 60 K, but below this temperature the material becomes

a semiconductor with a now quickly decreasing conductivity (Coleman *et al.*, 1973). The peak was interpreted as arising from superconducting fluctuations and the low-temperature semiconducting state resulting from a Peierls instability (see below). The reported unusually high-conductivity peak may have been a consequence of measurement errors easily encountered when dealing with highly anisotropic systems, but relative rise by a factor of 15–20 is usually found in pure crystals, and this is quite difficult to explain within a single electron scattering model.

26.3.2
One-Dimensional Physics and Instabilities

The Peierls instability is quite typical for a quasi-one-dimensional system like TTF–TCNQ and is seen in many similar materials. Hence, we will briefly describe the physics involved. The electronic structure of, for example, the TCNQ stack may be represented as shown in Figure 26.5.

As far as interstack interactions can be neglected, the one-electron band structure is truly one-dimensional. There is virtually no dispersion perpendicular to the stacks. Owing to the small electronic overlap along the stacks, a tight binding approximation is excellent and at low temperature the band is filled to the Fermi wave vector, k_F, which is at about 30% of the zone boundary. Peierls (1955) was the first to demonstrate that such a one-dimensional metal is unstable in the presence of a finite electron–lattice (–phonon) interaction. This is easily seen by considering the effect of a 2 k_F-potential on the electronic structure (see Figure 26.6).

The result is the opening of an energy gap, E_G, right at the Fermi level. From the density-of-states, it is evident that this new nonmetallic state has a lower electronic energy than the original metallic state shown in Figure 26.5. The system may introduce such a 2 k_F-potential through the electron–phonon coupling by creating a periodic lattice distortion. It can be shown that while the gain in energy will scale with $E_G{}^2 \ln(E_G)$, the cost in elastic energy only varies with $E_G{}^2$. Hence, the system is unstable for any magnitude of the electron–phonon coupling. It is important to emphasize that the instability depends on the ability for a potential at a single wave vector to open an energy gap over the entire Fermi surface. This may still be possible for a weak dispersion perpendicular to the chain direction but is not in two- or three-dimensional systems.

If 2 k_F is commensurate with the crystal lattice, the distortion will be locked to the underlying original lattice and a metal–insulator transition is predicted. However, if, as is the case

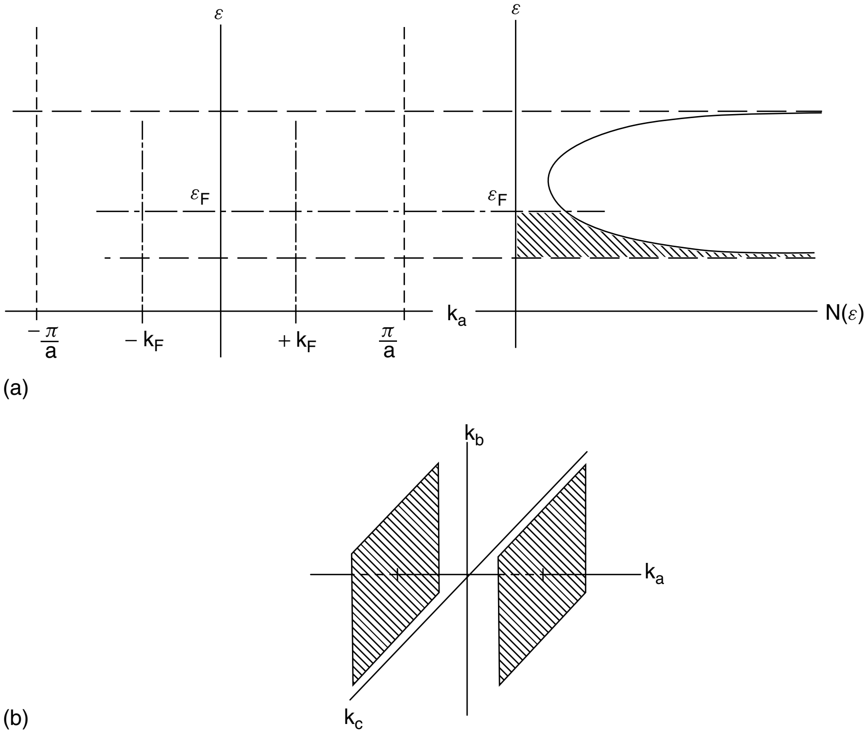

Fig. 26.5 (a) Quasi-one-dimensional electronic band structure in the TCNQ stack in TTF–TCNQ. The electronic wave number $k = 2\pi/\text{wavelength}$, while a is the lattice constant along the stack. The symbol ε is the one-electron energy. The right-hand drawing shows the density-of-states. The available states are filled to the Fermi level, ε_F, except for a thermal smearing of order a few kT. The corresponding wave number is k_F. (b) The Fermi surface (i.e. the transition between occupied and unoccupied states in **k**-space) simply consists of two planar and parallel sheets separated by 2 k_F.

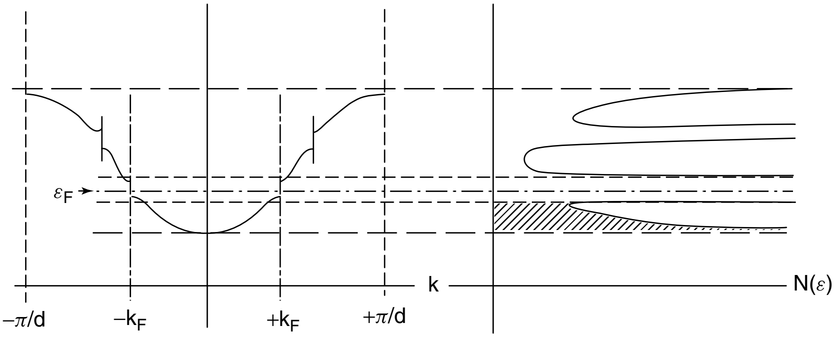

Fig. 26.6 Effect of a 2 k_F periodic lattice distortion along the stack on the quasi-one-dimensional band structure of the TCNQ stack in TTF–TCNQ. A gap opens over the entire Fermi surface and the electronic energy is lowered.

Singlet superconductivity (SS)
Charge-density wave (CDW)

Fig. 26.7 "G-ology" map of ground states in an idealized one-dimensional metal. The coupling constants g_1 and g_2 describe electron–hole interactions with momentum transfers near $2k_F$ and near 0, respectively.

with TTF–TCNQ, $2\,k_F$ is incommensurate with the underlying lattice, the energy of the lattice distortion is independent of the exact position along the stack, and the coupled electron–lattice distortion (called a charge-density wave (CDW)) may slide through the crystal without friction. Since the energy gap prevents scattering of the individual electrons, this is a mechanism for superconductivity, originally proposed by Fröhlich (1954). The sharp conductivity peak in TTF–TCNQ is sometimes attributed fully or partially to the Fröhlich mechanism. In any case, it simultaneously demonstrates that Fröhlich conductivity is susceptible to pinning both by defects and by ordering caused by three-dimensional interactions (e.g. Coulomb interactions). Any such effect will tend to lock the CDWs to the lattice, thus turning the material into an insulator. This is in contrast to the BCS mechanism for superconductivity, which is quite robust to nonmagnetic defects.

The CDW instability is just one example of possible instabilities in one-dimensional metals. Arbitrary electron–electron interactions may be assumed and characterized by two coupling constants g_1 and g_2. Owing to the one-dimensionality, low-energy electron– hole interactions are possible only with momentum transfers near $2\,k_F(g_1)$ and near 0 (g_2). Mean-field calculations then lead to a "phase diagram" for the ground state as schematically shown in Figure 26.7 (see, for example, Jerome and Schulz, 1982).

As is seen, spin-density waves (SDW) as well as CDWs, and both singlet and triplet superconductivity may be encountered. Again these ground states are genuine one-dimensional results, although the real systems when temperature goes to zero must always be influenced by three-dimensional effects.

Also it must be borne in mind that long range order in a one-dimensional system can only exist at zero temperature. Phase transitions will always involve higher dimensional effects, and hence the transitions tend to be suppressed significantly below the temperatures predicted by mean-field theories. In the temperature range between the mean-field scaling temperature and the real transition temperature, important one-dimensional fluctuations are likely to occur. This is presumably how the conductivity behavior of TTF–TCNQ should be understood. Between 60 and

150 K, the conductivity is enhanced by fluctuating short-ranged CDWs.

26.3.3
Quasi-One-Dimensional Organic Superconductors

Historically, superconductivity in organic crystals was first found in the Bechgaard salts $TMTSF_2X$, where X is an inorganic anion like PF_6^-, AsF_6^-, SbF_6^-, BF_4^-, NO_3^-, and so on (Bechgaard *et al.*, 1980). These are selenium-based sister compounds of the sulfur-based $TMTTF_2X$ family (Delhaes *et al.*, 1979). The characteristic crystal structure is shown in Figure 26.8. Apart from the electronic instabilities described below, those materials with less than octahedral symmetry of the anions are also prone to various anion ordering phenomena, which can have a drastic influence on the electronic properties (for an extended review see, for example, Jerome, 2004).

Again molecular stacks are formed, but because of the anions a zigzag pattern is seen. The overlap between stacks is small in the c'-direction (passing the anions), but may be considerable in the b'-direction. This is evidenced by

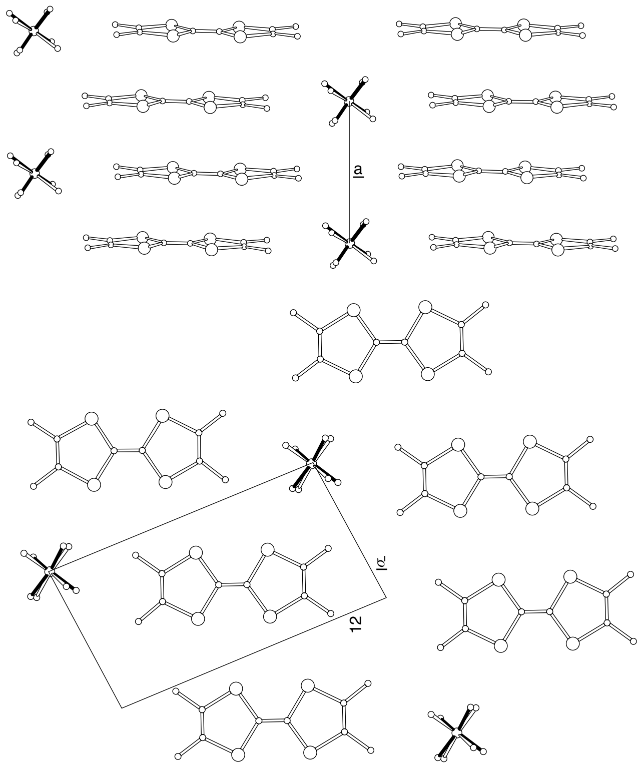

Fig. 26.8 Crystal structure of $TMTSF_2ClO_4$, the first ambient pressure organic superconductor. (a) Side view on the stacks and (b) view along the stacks. Two possible orientations of the perchlorate-ions are indicated. The ions are ordered in the superconducting state (Soling *et al.*, 1981).

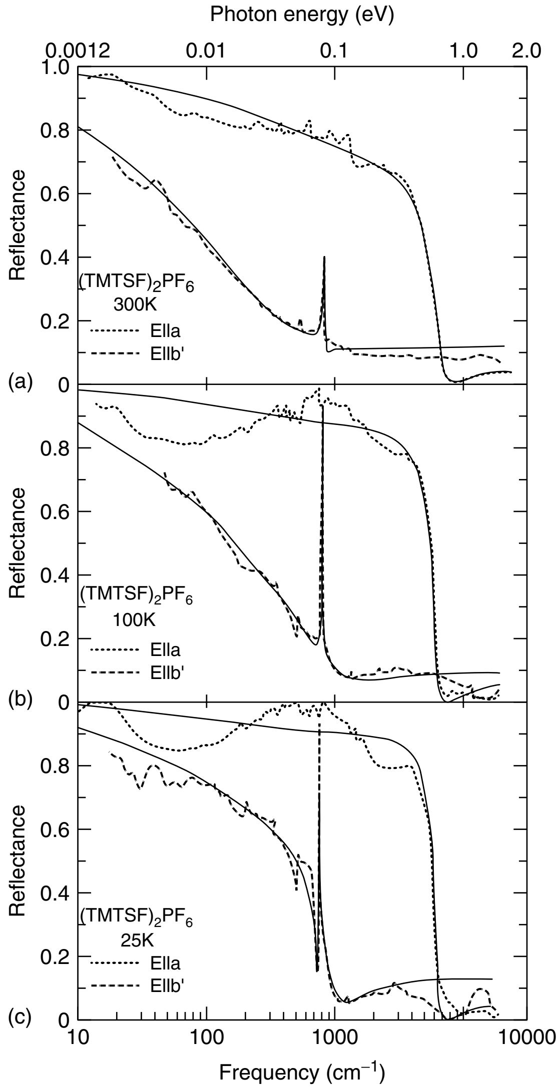

Fig. 26.9 Polarized infrared reflectance spectra of TMTSF$_2$ PF$_6$ at three temperatures: (a) 300 K, (b) 100 K, and (c) 25 K. The rise of a plasma edge along *b*′ is noted. The solid lines are Drude model fits (Reproduced with permission from Jacobsen, Tanner, and Bechgaard, 1981. Copyright American Physical Society.).

the optical reflectance studies shown in Figure 26.9, which in contrast to, for example, TTF–TCNQ and TMTTF$_2$X, show metallic reflectance both in the stacking direction and at low temperature in the *b*′-direction as well.

The data suggest a bandwidth anisotropy of order 10 and consequently a

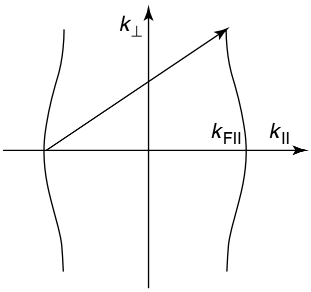

Fig. 26.10 Schematic drawing showing the warping of the Fermi surface (cross section shown) in the $TMTSF_2X$ conductors. The warping is due to significant interstack interactions.

warping of the Fermi surface such as that in Figure 26.10. Note that the Fermi surface is still open and may be almost completely nested by a single wave vector. Thus the basic electronic structure is still susceptible to the characteristic one-dimensional instabilities, and the materials are classified as being quasi-one-dimensional.

It is quite interesting to compare the isostructural $TMTSF_2X$ and the $TMTTF_2X$-families. Although the larger selenium atom gives a larger intermolecular overlap, the stacking axis bandwidth in the selenium-based compounds is just 20% bigger than it is in the sulfur-based compounds (Jacobsen, 1988). The main qualitative difference seems indeed to be in the interstack contacts, allowing coherent transport in the selenium-based family. The difference in transport properties is drastic. In Figure 26.11 we present the stacking axis resistivities as a function of temperature for $TMTSF_2$ PF_6 and $TMTTF_2$ PF_6.

The resistivity of $TMTTF_2$ PF_6 increases strongly on cooling, a behavior understood as being caused by a dominating short-range Coulomb interaction, which prevents delocalization of the charge carriers. It can also be described as a 4 k_F-instability and CDW, where the carriers correlate to stay apart (an equidistant arrangement of the charge carriers corresponds to a period $2\pi/4\ k_F$, forming what is named a *Mott insulator*). In contrast, $TMTSF_2$ PF_6 shows a metallic resistivity with an approximate T^2-dependence down to approximately 12 K, where a transition into a semiconducting 2 k_F-SDW state is found (for a review see Jerome, 2004).

Then in 1980 the finding of the first organic superconductor was reported. Jerome *et al.* (1980) discovered $TMTSF_2$ PF_6 to be superconducting at an elevated hydrostatic pressure of 900 MPa with a transition temperature of 1.0 K. Shortly after, the $TMTSF_2ClO_4$ compound, which due to a smaller anion has a slightly denser packing, was found to be superconducting at ambient pressure with a transition temperature of 1.2 K (Bechgaard *et al.*, 1981a, 1981b). Figure 26.12 shows measurements of the suppression of superconductivity by a small magnetic field perpendicular to the stacking axis.

The specific heat of the ClO_4 compound displays almost a textbook example of a superconducting transition (Garoche *et al.*, 1982). It may be analyzed to give a thermodynamic critical field of order 4 mT. However, this does not mean that the superconducting state in these materials is understood. Careful measurements have revealed that the critical magnetic fields, in particular, for fields

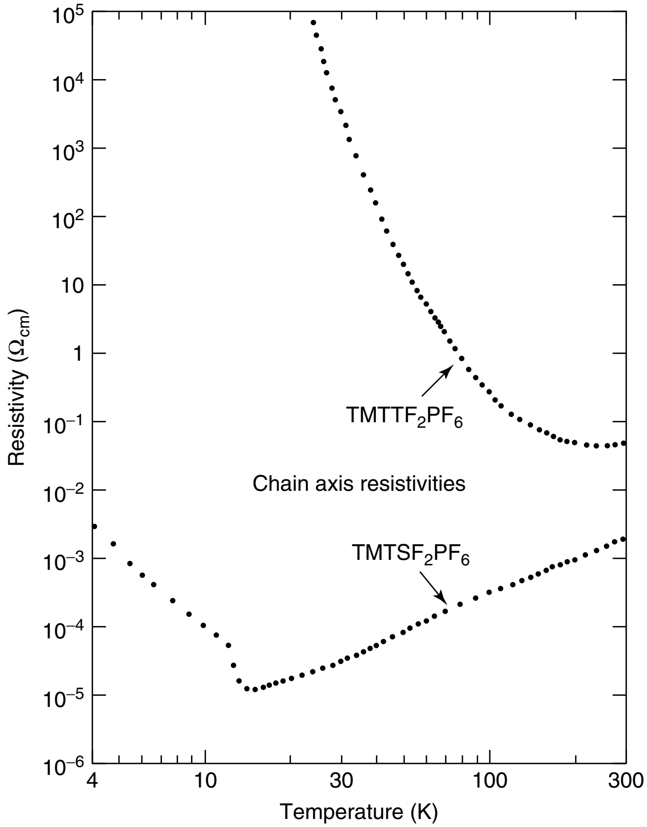

Fig. 26.11 Temperature-dependent resistivities of isostructural $TMTSF_2PF_6$ and $TMTTF_2PF_6$ at ambient pressure. Notice the logarithmic axes. The resistivity of $TMTSF_2PF_6$ shows an approximate T^2-dependence in the metallic state, and below about 12 K semiconducting behavior due to a frozen SDW state. The $TMTTF_2PF_6$-data bears evidence for the gradual Coulomb driven localization of the conduction electrons on cooling (Jacobsen, unpublished data).

along b' (where the interstack contacts are appreciable), are as large as 5–6 T (Lee *et al.*, 1997; Oh and Naughton, 2004). Thus the materials are extreme type II superconductors, and such values exceed the Pauli limit, where the pairing into singlet Cooper pairs should be destroyed by the field aligning the spins. It has therefore been taken as an argument for triplet superconductivity in these materials, where the spins are aligned in the BCS state. However, recent nuclear magnetic resonance (NMR) studies rather support the singlet-model (Shinagawa *et al.*, 2007). Another puzzling feature is a rather strong sensitivity of the superconductivity to nonmagnetic defects (see, for example, Jerome, 2004).

The nonconventional nature of superconductivity in TM_2X may very well be

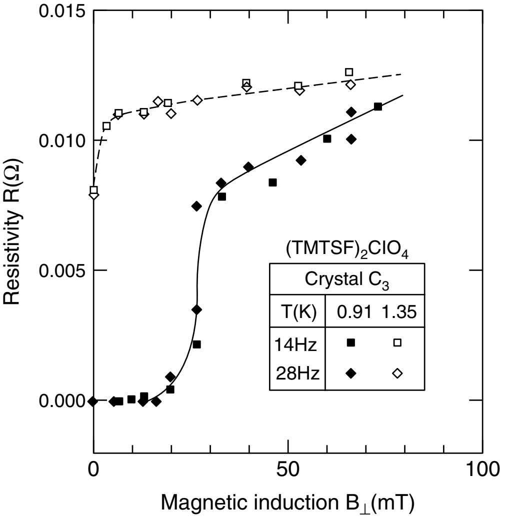

Fig. 26.12 Resistance of $TMTSF_2ClO_4$ as a function of a magnetic field perpendicular to the stacks for two temperatures, 0.91 K and 1.35 K, the latter being above T_C (Reproduced with permission from Bechgaard *et al.*, 1981b. Copyright American Physical Society.).

related to the occurrence of a whole range of interesting states in these materials. Jerome (1991) has suggested a generic pressure–temperature phase diagram for the family, which we reproduce in Figure 26.13. Ordered phases include superconductivity bordering to SDW formation, charge localization (described above), and the spin-Peierls state, where the spins in the charge localized state order with a 2 k_F-periodicity and quench the magnetic susceptibility. Also the whole picture is complicated by the occurrence of the so-called field-induced SDW states and quantum Hall effect states at fields in the 5–30 T range. In conclusion, these materials display very rich and challenging physics, which is yet to be understood.

26.3.4
Quasi-Two-Dimensional Organic Superconductors

An important modification of TMTTF results in the molecule bis(ethylenedithio) tetrathiafulvalene (BEDT–TTF or in brief ET, see Figure 26.3). It combines

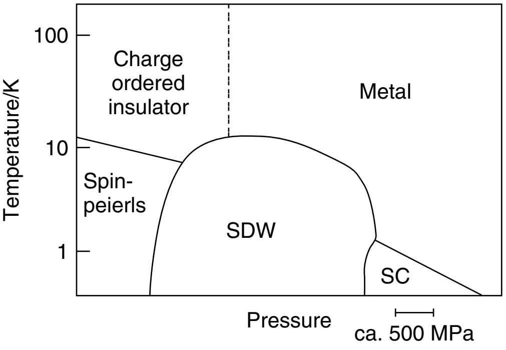

Fig. 26.13 Generic temperature–pressure phase diagram for the TMTT(S)F_2X conductors. SC, superconductivity and SDW, spin-density-wave state. $TMTTF_2PF_6$ is in the left part of the diagram, while $TMTSF_2ClO_4$ is in the right part (Adapted with permission from Jerome, 1991. Copyright American Association for the Advancement of Science.).

with various inorganic and organic anions to produce a variety of crystal structures, where those relevant for superconductivity have layered structures. The ET molecules order in stacks with appreciable contact between stacks. This is due to the high number of sulfur atoms along the periphery of the molecule (eight instead of four in TMTTF). This makes the electronic band structure effectively two-dimensional. This may be exemplified by the polarized reflectance spectra of β-ET_2I_3 shown in Figure 26.14. Analysis indicates a bandwidth anisotropy within the layer of $W_{\mathrm{stack}}/W_{\mathrm{perpendicular}} \approx 2$ (Jacobsen, Williams, and Wang, 1985; Jacobsen *et al.*, 1987), and suggests a closed Fermi surface in the layer plane, which cannot be nested by a single wave vector. Thus, such materials should not be susceptible to the typical quasi-one-dimensional instabilities (for an extended review see, for example, Singleton and Mielke, 2002).

The ET salts may be classified according to type of crystal structure, where those pertinent for superconductivity are named as α, β, β'', λ, and κ phases (Mori, 1998; Mori, Mori, and Tanaka, 1999; Mori, 1999). Only the β-phase has the simple two-dimensional Fermi surface described above. The others seem to possess both two-dimensional pockets and quasi-one-dimensional sections, thus again opening up for the possibility of for example, CDW formation (see, for example, Singleton, 2000, and Ishiguo, Yamaji, and Sauto, 1998).

Superconductivity at ambient pressure was first discovered in ET_2I_3 with $T_C = 1.4$–2.5 K (Yagubskii *et al.*, 1984). In the β-ET_2X family, it is observed that $T_C = 1.5$ K for $X = I_3^-$, $T_C = 2.7$ K for $X = IBr_2{}^-$, and $T_C = 4.9$ K for $X = AuI_2{}^-$ (see, for example, Ishiguo, Yamaji,

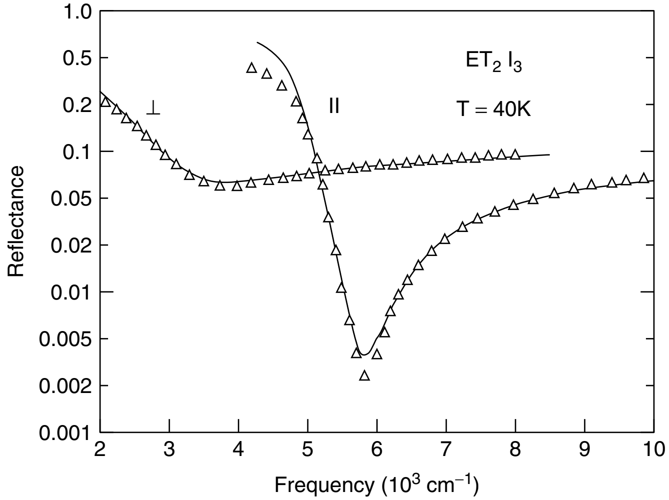

Fig. 26.14 Polarized infrared reflectance spectra of ET_2I_3 at $T = 40$ K. A distinct plasma edge is observed perpendicular to as well as along the molecular stacks. The solid lines are Drude model fits (Reproduced with permission from Jacobsen, Williams, and Wang, 1985. Copyright Elsevier.).

and Sauto, 1998). Hydrostatic pressure in general reduces T_C. Consistent with this, the highest transition temperatures in the ET family is found using rather large anions. Here, we just mention κ-ET$_2$Cu(NCS)$_2$ with $T_C = 10.4$ K (Urayama *et al.*, 1988; Carlson *et al.*, 1988) and κ-ET$_2$[N(CN)$_2$]Br with $T_C =$ 11.6 K (Kini *et al.*, 1990). Slightly higher values have been found using hydrostatic pressure. Altogether several tens of ET compounds have superconducting ground states and a variety of modified donor molecules have also been found to be superconductors (see, for example, Ishiguo, Yamaji, and Sauto, 1998).

The superconducting state has been investigated in detail, in particular, in the κ-family. Just as with the TMTSF-compounds, there is no consensus as to the detailed mechanism or the symmetry of the pairing. In the following, we just describe some typical characteristics.

Determination of the upper critical field in κ-ET$_2$Cu(NCS)$_2$ is hampered by motion of vortices in the mixed state but is in the range 3–8 T for fields perpendicular to the layers (for a review see Singleton and Mielke, 2002). For fields exactly in plane, the upper critical field is 35 T. Triangular vortex lattices have been seen.

Considerable discussion has centered around the symmetry of the order parameter (gap function, Δ). The standard *s*-wave order parameter is isotropic, and the gap is complete. Support for a completely gapped superconducting state comes from specific heat measurements on κ-ET$_2$[N(CN)$_2$]Br. They show a discontinuity and fit a theory for strong coupling superconductivity (Elsinger *et al.*, 2000). In contrast, *d*-wave symmetry is characterized by an anisotropic gap including nodes, where the gap goes to zero. Such *d*-wave symmetry is supported by NMR measurements. A detailed study on κ-ET$_2$[N(CN)$_2$]Cl is described by Lefebvre *et al.* (2000) as a function of temperature and hydrostatic pressure and apparently excludes *s*-wave symmetry. It also reveals an interesting phase diagram. Superconductivity exists above 30 MPa and below 13 K, while the ambient pressure ground state is antiferromagnetic. There is a first-order borderline between a magnetic phase and superconductivity with evidence for coexisting phases. While measurements of the penetration depth, which can also give indications about the gap, are rather inconclusive, tunneling experiments on κ-ET$_2$Cu(NCS)$_2$ have shown a convincing anisotropy (Arai *et al.*, 2001).

In conclusion, the superconducting members of the ET family are highly anisotropic type II materials. There is evidence for antiferromagnetic fluctuations playing a role in the pairing, and also for non-*s*-wave character of the order parameter. So while the situation is far from settled, these materials must also be placed in the category of unconventional superconductors.

26.4
Conclusion and Outlook

Almost 30 years after the discovery of the first organic superconductor, the microscopic mechanism is still not understood, and the area continues to attract many research groups throughout the world. The materials are similar to the ceramic high-temperature superconductors, which are also not understood, in the sense that superconductivity occurs next to magnetism. The richness of different ground states as well as the behavior in high magnetic fields also makes the materials group a favorite playground for physicists. The highest transition temperature in the charge transfer compounds is about 12 K, but without a detailed understanding of the phenomenon it is impossible to predict how high it can be.

To date no polymers has shown bulk superconductivity. Oxidized polypropylene films have been reported to show behavior that is interpreted as superconductivity at room temperature. However, the high conductivity is confined to narrow channels perpendicular to the films, and whether it has relation to BCS superconductivity is not so clear (see, for example, Grigorev, 1998).

Concerning biomolecules, speculations about superconductivity continue and the observation of signs of proximity induced superconductivity in micrometer DNA strings at ultralow temperatures suggests that it is a possibility (Kasumov *et al.*, 2001). The proximity effect exploits the fact that a superconducting order always to some extent leaks into a normal conductor, which is in close contact with the superconductor. In the present case, rhenium/carbon electrodes with $T_C = 1$ K were used. There is little doubt that efforts to map out the electronic quantum transport properties of macromolecules will continue.

Glossary

C-60: hollow spheres of 60 carbon atoms (“bucky balls”).

Carbon nanotubes: tubes formed as rolls of graphene. They can be single-walled as well as multiwalled and exist in both conducting and insulating forms.

Charge transfer complex: consists typically of pairs of donor and acceptor molecules, where a finite electron transfer takes place. It is one approach to create unpaired charge carriers in molecular crystals.

Conduction electrons: electrons that are not bound to the lattice sites but are free to move through the material.

Continuous phase transition: a phase transition without latent heat. Examples are ferromagnetism and superconductivity.

Density-of-states: number of allowed one-electron states per energy. It has a high value at the Fermi level in a metal and is zero within an energy gap.

Dissipation: loss of organized energy into heat. Example includes scattering of electrons caused by lattice vibrations leads to a loss of electric energy.

Energy band: description of one-electron quantum states in crystals. The energy band is the one-electron energy as function of wave number (or more generally wave vector). The states are so closely spaced that it is appropriate to talk about bands. There are a number of different bands making up the band structure.

Energy gap: range of energies, where no quantum states exist. It is typical for waves in periodic lattices. A material where the chemical potential is located in an energy gap is insulating or semiconducting.

Faraday’s law: the law of induction. A time-dependent magnetic flux generates an electric field circulating around it. The magnitude of the corresponding electromotive force equals the time derivative of the flux.

Fermi level: separates the occupied electronic states in a metal from those unoccupied. More precisely it is the low-temperature limit of the chemical potential.

Graphene: single carbon layer in graphite.

Mean-field theory: simple way of including ordering phenomena in statistical physics. The order is treated as an average field. Thus all fluctuations are neglected. It works rather well for superconductivity because of the finite coherence length.

Momentum: mass times velocity. In the presence of a magnetic field, it is necessary to distinguish between this kinematical momentum and the canonical momentum, which depends on the field and is present in the equations of motion.

Mott insulator: material with a finite one-electron density-of-states at the chemical potential, which, nevertheless, is semiconducting or insulating owing to important short-range Coulomb repulsion between the electrons.

Orbital symmetry: symmetry of wave function. For superconductivity, it often refers to the symmetry of the Cooper pairs (using the language of atomic physics: s-wave, p-wave, d-wave, etc.).

Organic molecule: molecule based on carbon chemistry. Pure forms of carbon are excluded.

Pauli principle: the principle states that a full one-electron quantum state (including spin) can house zero or one electron.

Persistent current: dissipation free current in a closed loop. In superconductors they have been observed running for years with negligible decay.

Phonon: quantized crystal lattice vibration.

π -bond: chemical bond formed from overlap of p-type orbitals perpendicular to the connection line between the nuclei. Example includes benzene.

Plasma edge: the sharp fall of reflectance of a metal at a frequency, where wave propagation sets in. It coincides with the plasmon frequency, that is, the frequency of electronic density oscillations. The plasma edge is often well described by a classical Drude model.

Polyene: unsaturated organic compound that contains one or more sequences of alternating double and single carbon–carbon bonds.

Proximity effect: leaking of superconductivity into a nearby normal metal in good contact with the superconductor. It is caused by second-order quantum processes.

Resistance: the ratio of the voltage drop across a conductor and the resulting electric current. According to the widely valid Ohm's law, the two quantities are proportional. A superconductor has zero resistance.

Semiconductor: material with a relatively small energy gap at the chemical potential. Hence, charge carriers can be generated easily thermally or by chemical or electrical control.

Superconductor: material that loses its resistivity completely below a critical temperature, T_C. In the superconducting state small magnetic fields are expelled.

Tight binding approximation: method of calculating the electronic band structure. It only includes the nearest neighbor interactions and works well for molecular crystals.

Wave number: one of the quantum number for free electrons and electrons moving in a periodic potential. The magnitude equals 2π divided by the wave length. In a crystal, it is generalized to a wave vector.

28.1
Introduction

After the inelastic scattering of light by molecules was predicted theoretically, the effect was observed experimentally in 1928 by the Indian physicist C.V. Raman. In honor of his discovery, the effect was named after him. In the past 80 years, the method was applied in various disciplines such as condensed matter physics and organic and inorganic chemistry. One field which gained significant recognition in the past 10 years was the application of Raman spectroscopy in medicine to assess cells and tissues. The principle of the Raman effect is that an excited photon interacts with a molecule, and an emitted photon possesses a different energy. The energy difference excites a molecular vibration. In this way, a set of vibrations, called Raman spectrum, can be obtained, which provides a highly specific fingerprint of the sample. In contrast to other photon emitting techniques such as fluorescence or phosphorescence, Raman spectroscopy offers the following advantages: (i) No labels are required, which suffer from limited stability and accessibility because vibrations are an inherent property of all molecules. (ii) The number of vibrations can be calculated from the number of atoms N by the formula $3N - 6$. Therefore, the number of Raman bands is much larger than the number of fluorescence bands, which depend on electronic transitions. (iii) As Raman bands are narrower, many bands can be resolved giving detailed information of the chemical composition and structure of samples. Molecular vibrations can also be excited by absorption of radiation in the mid infrared (IR) wavelength range between 2.5 and 25 μm. However, the prospects of Raman spectroscopy in medicine have been recognized to be superior compared with IR spectroscopy mainly due to easier sample preparation and the tolerance of spectral contributions from the most abundant biomolecule water. The principle of Raman spectroscopy to study cells and tissues is that diseases and other pathological anomalies cause chemical and structural changes at the molecular level. These changes also alter the Raman spectra that can be used as sensitive phenotypic marker. First, the current contribution describes the technical progress that was required before Raman spectroscopy could be applied to cells and tissues that are composed of thousands of biomolecules in a complex way. Then, medical applications are summarized, which complement pathology

to assess tissue *ex vivo* and *in vivo*, and clinical chemistry to determine the composition of body fluids.

28.2
Raman Instrumentation for Medical Applications

The basic setup of a dispersive Raman spectrometer consists of a laser as an intense and monochromatic light source, a device that separates the elastically (Rayleigh) scattered light of the sample from the Raman (inelastically) scattered light, a spectrograph and a detector. Multichannel detectors enable to register the whole Raman spectrum simultaneously within a fraction of seconds. Raman spectrometers utilizing the Fourier transform (FT) principle consist of an interferometer instead of a spectrograph. The interferometer converts the Raman scattered radiation into an interferogram, which is registered by a fast detector. After Fourier transformation of the interferogram, the whole Raman spectrum can be obtained.

28.2.1
Raman Spectra of Biomolecules

Starting point for medical applications of Raman spectroscopy is to study the Raman spectra of the main constituents of cells and tissues such as proteins, nucleic acids, and lipids. Representative spectra of purified samples are shown in Figure 28.1. In general, the spectra depend on the monomeric units

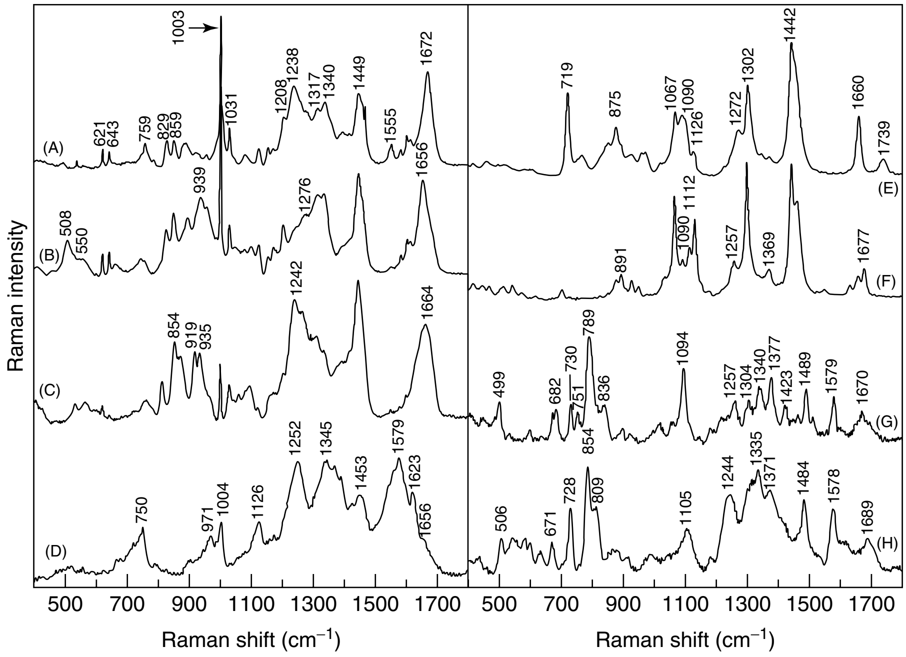

Fig. 28.1 Raman spectra from 400 to 1800 cm^{-1} of proteins (A, B, C, D), lipids (E, F), and nucleic acids (G, H): concananvalin A (A), serum albumin (B), collagen type 1 (C), hemoglobin (D), phosphatidylcholin (E), galactocerobroside (F), DNA (G), and RNA (H).

(amino acids in case of proteins and nucleotides in case of nucleic acids) and the geometry of the backbone. Bands in the Raman spectrum of the all β-protein concanavalin A (spectrum A) are assigned to phenylalanine (621, 1003, 1031, and 1208 cm^{-1}), tyrosine (643, 829, and 853 cm^{-1}), tryptophan (759, 1340, and 1555 cm^{-1}), $\mathrm{CH}_{2/3}$ of aliphatic amino acids (1317 and 1449 cm^{-1}), and amide I (1672 cm^{-1}) and amide III (1238 cm^{-1}) of the peptide backbone. Additional bands at 508 and 550 cm^{-1} in the Raman spectrum of the all α-protein serum albumin (spectrum B) are indicative of disulfide bonds that stabilize the protein structure. Amide I and III bands are shifted to 1656 and 1276 cm^{-1}, respectively. Together with the band at 939 cm^{-1}, they are typical for α-helices. Increased bands at 854, 919, 935, 1242, and 1664 cm^{-1} are observed in the Raman spectrum of collagen (spectrum C) due to the triple helix structure and the unusual amino acid composition, which contains high content of prolin and hydroxyprolin. As bands of the cofactor heme in the Raman spectrum of hemoglobin are enhanced at 750, 971, 1004, 1126, 1252, 1453, 1579, and 1623 cm^{-1}, they are more intense than the amide I band of the protein at 1656 cm^{-1} (spectrum D). The enhancement effect is described in Section 28.2.6. As the heme group is important for the function of the protein and Raman spectroscopy can sensitively probe the vibrations of the heme group, this method has frequently been applied to this group of proteins (Wood and McNaughton, 2006).

Lipids are composed of a backbone group, a hydrophobic moiety that is often a long fatty acid chain, and a hydrophilic moiety that is derived from a sugar or alcohol compound. The Raman spectrum of phosphatidylcholine (spectrum E) shows bands due to fatty acids (1067, 1126, 1302, and 1442 cm^{-1}), the choline group (719 and 875 cm^{-1}), the phosphate group (1090 cm^{-1}), and the ester group (1739 cm^{-1}). Bands at 1660 and 1272 cm^{-1} indicate unsaturated fatty acids chains. The Raman spectrum of galactocerobroside shows similar fatty acids bands (spectrum F). However, the ceramide backbone instead of the glyceride backbone is characterized by amide I and III bands near 1677 and 1257 cm^{-1}, respectively. The galactose ring instead of the phosphorylated choline group is characterized by bands at 891, 1090, 1112, and 1369 cm^{-1}. Raman spectra of other lipids have previously been reported (Krafft *et al.*, 2005a).

Bands in the Raman spectrum of DNA (spectrum G) are assigned to the nucleotides bases guanine, adenine, thymine, and cytosine (499, 682, 730, 751, 789, 1257, 1304, 1340, 1377, 1489, 1579, and 1670 cm^{-1}), the phosphodiester groups (836 cm^{-1}), and the phosphodioxy groups (1094 cm^{-1}) in B-form geometry. Changes in the Raman spectrum of RNA (spectrum H) are consistent with a different sugar pucker geometry, the nucleotide base thymine is replaced by uridine, and the phosphate backbone adopt a A-form geometry, which shift the bands to 809 and 1105 cm^{-1}. Details of the band assignment can be found elsewhere (Prescott, 1984).

28.2.2
Near-Infrared Advantage

Raman spectroscopy of natural, unprocessed biological material is more complicated because spectral contributions of all molecules overlap and intrinsic fluorescence often masks the weaker Raman signals when using visible lasers for excitation. Even trace amounts of fluorescent material can cause an intense signal due to several orders of magnitude larger efficiency. As most tissues and body fluids show minimum absorption in the wavelength interval from 700 to 900 nm, the excited autofluorescence is at minimum and the penetration of the exciting and scattered radiation is at maximum. Fluorescence in Raman spectra can also be avoided by laser excitation in the deep ultraviolet (UV) because a fluorescence-free window exists with excitation below 270 nm. However, deep UV excitation also harbors the risk of inducing photodegradation damage, which should be avoided in *in vivo* situations.

In the late 1980s, near-infrared (NIR) FT-Raman spectrometers with Nd-YAG laser excitation at 1064 nm have been developed to overcome the fluorescence problem. Because the scattering intensities decrease with the forth power of the frequency of the exciting radiation, the Raman signals were $2^4 = 16$ times less intense compared with 532 nm excitation. Together with the low sensitivity of the FT-Raman spectrometers and the low Raman cross-sections of most biomolecules, collection times were impractically long. Since the mid 1990s, high-throughput optical elements for Rayleigh scattering rejection (notch or edge filters) and for spectral dispersion (holographic transmissive gratings) have been introduced in Raman spectrometers. In combination with NIR lasers emitting at or near 785 nm and sensitivity-optimized, silicon-based charge-coupled device (CCD) detectors, these Raman systems enabled collecting Raman spectra of unprocessed biological material in the spectral range from 200 to 3600 cm^{-1} within seconds.

28.2.3
Raman Microscopy

The coupling of a Raman spectrometer with a microscope offers two main advantages. First, lateral resolutions can be achieved up to the Abbe's limit of diffraction below 1 μm. This property is important to resolve subcellular details in single cells. Even lower resolutions have been demonstrated using near field microscopic approaches. As a consequence of their complexity, these techniques have not been applied in medicine yet. High axial resolutions are obtained by confocal microscopes. Secondly, maximum sensitivity can be achieved because the photon flux (photon density per area) at the focused laser beam onto the sample is at maximum and the collection efficiency of scattered photons from the sample is at maximum. The lateral resolution, the diameter of the focus, and the collection efficiency depend on the numerical aperture (NA) of the microscope objective, which is the product of the sine of the aperture angle and the diffraction index. High NA objectives have small working distances below 1 mm in air. The working distance of water immersion objectives can be larger due to the larger diffraction index of water. Oil immersion objectives in combination with oil should be avoided because the oil can contaminate the sample and the spectral contributions of oil overlap with the Raman spectrum of the sample.

28.2.4
Raman Imaging

Raman imaging combines the spectral and the lateral information. Most Raman images are collected in the point-mapping mode. Here, the laser is focused onto the sample, the scattered light is registered, and subsequently the focus is moved by a scanning mirror or the sample is moved by a motorized stage to the next position. The total exposure time depends on the number of spectra and the exposure time per spectrum. Accumulating more than thousand spectra with typical times of a few seconds per spectrum usually takes hours. In the case of laser line illumination of the sample, the spatial data can be registered on the detector on a line parallel to the entrance slit of the spectrometer and the spectral information is dispersed perpendicularly. The second spatial dimension of an image is recorded by scanning in the direction perpendicular to that line. This so-called line-mapping registration mode is faster because only one dimension instead of two dimensions in the point-mapping mode has to be scanned. The parallel registration approaches called direct or wide-field Raman imaging employs intense, global sample illumination. The inelastically scattered light from the sample is projected onto a two-dimensional CCD detector. Most wide-field Raman imaging spectrometers use filters to select the wavelength such as dielectric, acousto-optic tunable, and liquid–crystal tunable filters. Although Raman spectrometers using this principle are commercially available (Falcon by Chemicon, USA), medical applications have not been reported yet.

28.2.5
Fiber-Optic Probes

In vivo diagnostic tools are much needed in many fields of medicine such as the guidance of surgical interventions to delineate lesions margins or to replace random biopsies of suspicious tissues by targeted biopsies that, in turn, would reduce unnecessary tissue excisions, pathology costs, and biopsy-associated risks. Several probe geometries have been designed for use with Raman spectrometers. A miniaturized probe that consisted of one central excitation fiber, six surrounding collection fibers, internal "in the tip" filters, and beveled fiber ends for optimized light collecting efficiency was designed (Shim *et al.*, 1999) and applied in various biomedical studies (Bakker Schut *et al.*, 2000; Boere *et al.*, 2003; Buschmann *et al.*, 2000; Crow *et al.*, 2005; Molckovsky *et al.*, 2003; Shim *et al.*, 2000). A micro-optical fiber probe for use in an intravascular Raman endoscope has been developed, which consists of one excitation fiber, eight collection fibers, integrated filters, and a lens (Komachi *et al.*, 2005a. Its total diameter is just 600 µm. Its use has been reported in two studies (Hattori *et al.*, 2007; Komachi, Sato and Tashiro, 2006). Other Raman probes that are, however, not commercially available use 15 fibers and a ball lens (Motz *et al.*, 2004), six fibers (Barbosa *et al.*, 2002) or one fiber for signal collection (Huang *et al.*, 2001; Mahadevan-Jansen *et al.*, 1998; Utzinger *et al.*, 2001). A probe with integrated filters, one excitation and one collection fiber each from Inphotonics Inc. (USA) was recently applied to record Raman images of murine brains (Krafft *et al.*, 2007). However, probe dimensions

(13 mm diameter, 100 mm length) are likely too large for endoscopic applications. A small, unfiltered probe was suggested as an alternative, because silica with a low content of hydroxyl groups as core material shows only low spectral contributions in the high wavenumber region from 2400 to 3800 cm^{-1} (Santos *et al.*, 2005). Other new developments include the PhAT probe from Kaiser Optical System (USA) with global illumination and an array of 50 collection fibers (Schulmerich *et al.*, 2006), hollow-core photonic crystal fiber-optic probes (Konorov *et al.*, 2006), a single flexible hollow waveguide coated with a silver film (Komachi *et al.*, 2005b), and concentric rings of optical fibers used in spatially offset Raman spectroscopy (SORS) (Matousek *et al.*, 2006). In SORS, Raman spectral contributions from subsurface layers can be obtained depending on the distance between the excitation and collection fibers.

28.2.6
Resonance Raman and Surface-Enhanced Raman Spectroscopy

Raman signals can be enhanced by various nonlinear techniques using ultrashort (femtoseconds), but high-intensity (megawatt) laser pulses. As they have not been applied in medicine so far, they are not within the scope of this chapter. However, resonance Raman spectroscopy (RRS) and surface-enhanced Raman spectroscopy (SERS) are variations of conventional Raman spectroscopy that can be used to enhance its specificity and sensitivity. In SERS, surface plasmons of rough metal surfaces (often gold or silver nanoparticles) are excited by the laser resulting in an increase in the electric fields surrounding the metal. Given that Raman intensities are proportional to the electric field, the measured signal of molecules that are adsorbed on these nanoparticles can be strongly increased (by up to 10^{15}) (Nie and Emory, 1997). Most plasmon frequencies are found in the visible range. In resonance Raman (RR), the excitation wavelength is matched to an electronic transition of the molecule, so that vibrational modes associated with the excited state are enhanced (by as much as a factor of 10^6). Electronic transitions of nucleic acids and proteins without prosthetic groups are found below 280 nm. The enhancement is restricted to vibrational modes of the chromophore, which reduces the complexity of large biomolecules. Both effects can be combined in surface-enhanced resonance Raman spectroscopy (SERRS) giving even higher enhancement factors.

28.3
Raman Spectroscopy in Pathology

Disease diagnosis generally involves gross and microscopic visual examination of tissues with special stains employed to visualize specific proteins and other substances. Rudolf Virchow (1821–1902) is generally recognized to be the father of microscopic pathology. Although the microscope has been invented earlier, Virchow was one of the first prominent physicians to emphasize the study of manifestations of disease, which were visible only at the cellular level. Virchow's student Julius Cohnheim (1839–1884) combined histology techniques with experimental manipulations making him one of the first experimental pathologists. Cohnheim also pioneered the use of the frozen section.

A version of this technique is still widely employed by modern pathologists to render diagnosis and provide other clinical information. New research techniques, such as electron microscopy, immunohistochemistry, and molecular biology, have expanded the means by which biomedical scientists can study disease. Raman spectroscopy has been combined with microscopy to complement microscopic pathology. As combination with fiber-optic probes enables applying the method under *in vivo* conditions, Raman spectroscopy is one of the optical methods currently under investigation for improvement of endoscopic applications, such as elastic light scattering, optical coherence tomography (OCT), and fluorescence spectroscopy.

28.3.1
Oncology

This section summarizes the prospects of Raman spectroscopy in oncology. As carcinoma, which is the collective term for tumors of epithelial tissue, constitutes the largest group of malignant tumors, Raman spectroscopy has frequently been applied for their detection. Before carcinomas of the gastrointestinal tract, breast, lung, urinary tract, and cervix uteri are discussed, the concepts of Raman spectroscopy in oncology is demonstrated in the context of neuro-oncology, which was previously described in detail (Krafft and Salzer, 2008).

28.3.1.1 Neuro-Oncology

Brain tumors are generally divided into primary and secondary brain tumors. According to a recommendation of the World Health Organization (WHO) (Kleihues and Cavenee, 2000), primary tumors that begin in brain tissue are classified by the cell types from which they originate, which include glial cells, neurons, the meninges, and cells of the pituitary gland. Astrocytic gliomas originate from astrocytes, a special class of glial cells. They account for approximately 50% of all primary brain tumors in adults and are classified by increasing malignancy into grade II (diffuse astrocytoma), grade III (anaplastic astrocytoma), and grade IV (glioblastoma multiforme, GBM). GBM either progresses from diffuse astrocytomas (secondary GBM) or arises *de novo* (primary GBM). Meningeomas are the second most frequent intracranial tumors after gliomas and account for approximately 20% of all primary brain tumors. They originate from the brain encapsulating meninges and form several subtypes, most of which are histologically benign (grade I): they exhibit slow growth pattern, and usually do not infiltrate brain tissue or cause metastases. Metastasis is the spread of cancer. Cancer that begins in other parts of the body may spread to the brain and cause secondary brain tumors, also called brain metastases. Brain metastases occur in about 15–40% of all cancer patients. This proportion has increased in recent years partly due to the increased sensitivity of tomographic techniques to detect these tumors, and also to the longer survival of these patients. The diagnosis of brain metastasis in a patient with a known systemic cancer is a simple matter. However, in almost 50% of patients undergoing surgery for brain metastases, the secondary brain tumor represents the first indication of cancer and the primary tumor is not known at the time of neurosurgery. Therefore, besides tumor resection, the scope of neurosurgical procedures is to collect tissue specimens for diagnosis. Nevertheless, in up to 15% of the patients with brain metastases the primary tumor will not be identified despite thorough investigation by standard screening techniques. Thus, brain metastases with unknown primary tumors are estimated to be almost equal in number to primary brain tumors (Polyzoidis, Miliaras and Pavlidis, 2005).

Histopathologic diagnosis of hematoxylin and eosin (H&E) stained tissue sections is the so-called golden standard to determine grade and type of the tumor, which decide its effective management and provide an indication of the prognosis. The location and the size of the brain tumor are determined by computed tomography (CT), magnetic resonance tomography (MRT), or positron emission tomography (PET), which usually require contrast enhancing agents. In spite of all the advances in understanding the pathomechanism, tomographic imaging, and availability of new therapeutic tools, treatment of cancer in the brain is one of the most challenging problems in oncology as well as neurosurgery. The medial survival rate of patients with GBM of 12 months has been prolonged only slightly and cure remains elusive. The typical median survival is more than five years for grade II gliomas and two to five years for grade III gliomas. None of the currently available surgical tools, including operative microscopy, lasers, and image-guided surgery, enable detection and removal of all tumor tissue. There are several success stories in treatment of other cancers, but similar success has not been achieved for GBM. Characteristics of GBM that hinder efforts to cure it include the following: (i) access of chemotherapeutic agents to the tumor is more restricted than to other organs due to the blood–brain and blood–tumor barriers; (ii) aggressive local spread and diffuse infiltrating growth of the tumor; (iii) location of the tumor within the brain obviates radical extirpation; (iv) the residual tumor grows rapidly and resists curative treatment. Management of gliomas encompasses surgery to establish the histological diagnosis and to reduce the tumor burden and the mass effect, with the maintenance of the patient's neurological function in mind. Tissue autofluorescence was suggested to distinguish brain tumors from normal brain tissue by their reduced fluorescence emission (Goujon *et al.*, 2003). False positive assignments were problematic as not all regions with reduced autofluorescence were tumorous. In order to improve the selectivity, clinical studies were performed using a combination of autofluorescence and diffuse reflectance (Toms *et al.*, 2005). A multicenter clinical study used a fluorescence marker to guide the tumor resection intraoperatively (Stummer *et al.*, 2006). It could be demonstrated that more radical tumor resection leads to a slower regrowth of the tumor. However, the medial survival rate did not change significantly, probably because recurrences were formed by tumor cells that were not labeled by the marker and thus could not be detected. Here, false negative assignments were problematic as not all regions without fluorescence were normal. Raman spectroscopy has been suggested to improve both the selectivity and sensitivity as it does not depend on exogenous markers to characterize tissue.

In a first set of Raman studies, consecutive thin tissue sections were prepared. One section was transferred onto a glass slide, stained by H&E and served as a reference to select regions of interest before data acquisition. Another section was transferred onto slides made of quartz, calciumfluoride, or bariumfluoride, which exhibit lower background signals with 785 nm excitation than glass. Alternatively, the unstained tissue section can be stained for histopathological analysis after data acquisition. It is important to prepare the tissue as cryosection without embedding the sample in paraffin. Paraffin penetrates the sample and causes intense overlapping spectral contributions. Removal of paraffin in tissue sections by organic solvents should be avoided as it also dissolves hydrophobic components such as lipids. Raman maps of GBM tissue sections from 20 patients were collected (Koljenovic *et al.*, 2002). Vital tumor was discriminated from necrotic tissue by lower spectral contributions of lipids. Raman maps of dura and meningeoma tissue sections from 20 patients were collected (Koljenovic *et al.*, 2005a). Raman spectra of dura and meningeoma were distinguished by high collagen content of dura and increased lipid content of tumors. Raman and Fourier transform infrared (FTIR) spectroscopy mapping of human primary brain tumors were compared for three tissue sections (Krafft *et al.*, 2006). Smaller details such as cell nuclei and microcrystals were better resolved in Raman maps than in FTIR maps. The formation of microcrystals was an artifact, which was induced in hydrophobic constituents such as cholesterol or cholesterol ester by the drying process. Raman maps were also obtained from tissue sections of rat brains with tumors (Andrade *et al.*, 2007). Here, healthy tissue was discriminated from tumor and necrotic tissue. The abovementioned studies used the algorithm cluster analysis to segment the spectra into groups of similar spectral response. Details of clustering algorithms to analyze vibrational spectroscopic images have been reported elsewhere (Lasch *et al.*, 2004) and will not be described in this chapter.

Figure 28.2 shows a photomicrograph and a 56 × 11 Raman map of a meningeoma section. The sample area was raster scanned with a step size of 100 μm. Before cluster analysis, low-quality and low-intensity spectra were removed from the data set. Their positions are represented by white pixels. The remaining spectra were segmented into five groups by k-means clustering. The gray scaled plot of the cluster membership is shown in Figure 28.2b. The average spectra of each cluster are displayed in the bottom part of Figure 28.2. Spectrum 2C representing the dark gray cluster contains spectral contributions of collagen at 858, 941, 1249, and 1666 cm^{-1} (compare with spectrum 1C of Figure 28.1). In spectrum 2D, representing the light gray cluster, the intensities of collagen bands are reduced and the bands of α-helical and β-sheet proteins dominate with an amide I band at 1660 cm^{-1}. In spectrum 2E, representing the light gray shaded cluster, spectral contributions of DNA are more intense than in spectrum 2D. The distinction of both the clusters demonstrates that even small differences can be detected if the signal-to-noise ratio is sufficiently high. As spectral contributions of collagen are even more intense in normal dura (Krafft *et al.*, 2005b), the dark gray cluster is assigned to meningeoma with higher collagen content and the light gray cluster is assigned to meningeoma with

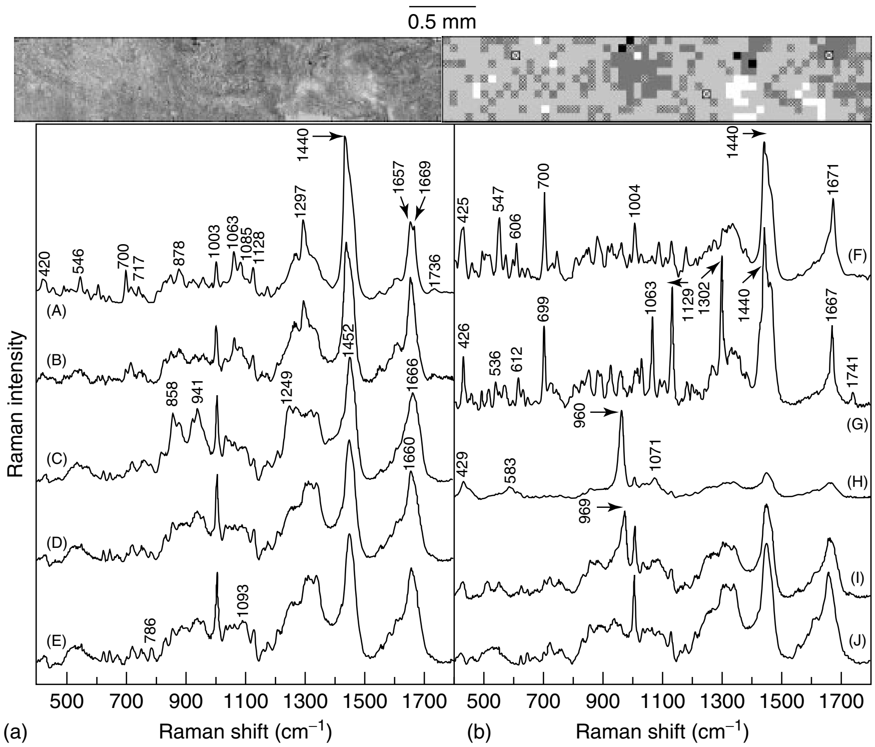

Fig. 28.2 (a) Photomicrograph and (b) cluster analysis of 56 × 11 Raman map of a meningeoma tissue section. Raman spectra from 400 to 1800 cm^{-1}: white (A) and gray (B) matter of normal brain tissue, meningeoma with higher collagen content (C), meningeoma with lower collagen content (D), meningeoma with higher DNA content (E), cholesterol microcrystal (F), cholesterol ester microcrystal (G), hydroxyapatite in brain tumor (H), calcium oxalate in brain tumor (I), glioblastoma multiforme (J).

low collagen content. Two additional spectral signatures are identified. Spectrum 2G representing the white crossed cluster resembles the Raman spectrum of almost pure cholesterol ester showing fatty acid bands (1063, 1129, 1302, and 1440 cm^{-1}), the ester band (1741 cm^{-1}), and bands near 425, 547, 606, 1671 cm^{-1}. This spectrum can clearly be distinguished from the Raman spectrum of cholesterol (spectrum 2F), which is often identified in normal brain tissue. Spectrum 2H representing the black cluster contains an intense band at 960 cm^{-1}, which is indicative of hydroxyapatite. Another stretching vibration band of hydroxyapatite is found at 1071 cm^{-1}, bending vibrations are located at 429 and 583 cm^{-1}. Calcification has also been observed in one of the first Raman studies of brain tumors (Mizuno *et al.*, 1994). The shift of the calcium phosphate band to 969 cm^{-1} in spectrum 2I is typical for calcium oxalate. The vibrational bands of calcium phosphate crystals were previously reviewed (Koutsopoulos, 2002). Calcification of tissue is not an unusual phenomenon in pathological tissues.

Calcium phosphates are formed as a result of functional irregularities and can be used as a marker to distinguish the pathological state and the type of tumors. For comparison, Raman spectrum of white matter (spectrum 2A) and gray matter (spectrum 2B) are included in Figure 28.2. These spectra represent the most abundant tissue types in normal brain. Spectral contributions of cholesterol are very intense in the spectrum of white matter, whereas they are less intense in the spectrum of gray matter. Both spectra are characterized by high lipid content, which offers the possibility to identify abnormal brain tissue including brain tumors. These results clearly demonstrate that the Raman spectrum provides a sensitive signature of tissue without additional markers, which can be used to analyze the chemical composition and determine the tissue type with supervised classification models.

In the second set of papers, nondried brain tissue has been studied by Raman spectroscopy. These experiments are important prerequisites to transfer the results from dried tissue sections toward *in vivo* applications. Seven Raman maps of native, human brain specimens were collected *ex vivo* using a Raman spectrometer coupled to a microscope and a motorized stage (Krafft *et al.*, 2005b). Normal white matter was confirmed to contain maximum lipid content, normal gray matter maximum water content, normal meninges maximum collagen content, and brain tumors lower lipid content. The methodology was modified to acquire Raman maps from whole murine brains (Krafft *et al.*, 2007). Instead of a microscope, the Raman spectrometer was coupled to a fiber-optic probe. The data coincided well with FTIR images from consecutive unstained tissue sections and with photomicrographs from consecutive H&E stained tissue sections. Brain metastases of malignant melanoma were detected in Raman maps.

The setup was applied to study brain tumors for the first time in a living mouse as shown in Figure 28.3a. The mouse was anesthetized and a cranial window made of CaF_2 was inserted onto the skull. The mouse was placed on a motorized table and a Raman map was collected from a predefined grid with 2 seconds exposure time per spectrum until the mouse awoke from anesthesia. The Raman spectra were segmented into the following groups by cluster analysis (Figure 28.3b): normal brain tissue (blue, cyan), bone (brown), the midline which contained blood (black), and brain metastases from malignant melanoma (red). The cluster distribution below the dashed line seems to be affected by motion artifacts of the animal. The cluster-averaged spectra representing each tissue type are shown in Figure 28.3c. The unprocessed spectra also contain the high wavenumber region from 1800 to 3550 cm^{-1} with the OH stretching vibrations of water near 3400 cm^{-1} and the CH stretching vibration at 2939 cm^{-1}. Owing to the high similarity of all spectra, the high wavenumber region is recognized to be less relevant for tissue recognition. The tumor detection in the low wavenumber region was facilitated by resonance enhancement of the Raman signals from melanin near 1600 cm^{-1} because the metastatic cells express this pigment. As a consequence of the inoculation of tumor cells in the carotid artery, the tumor was located in one brain hemisphere (here: left), whereas the other brain hemisphere (here: right) was tumor-free. The Raman band at 960 cm^{-1} is consistent

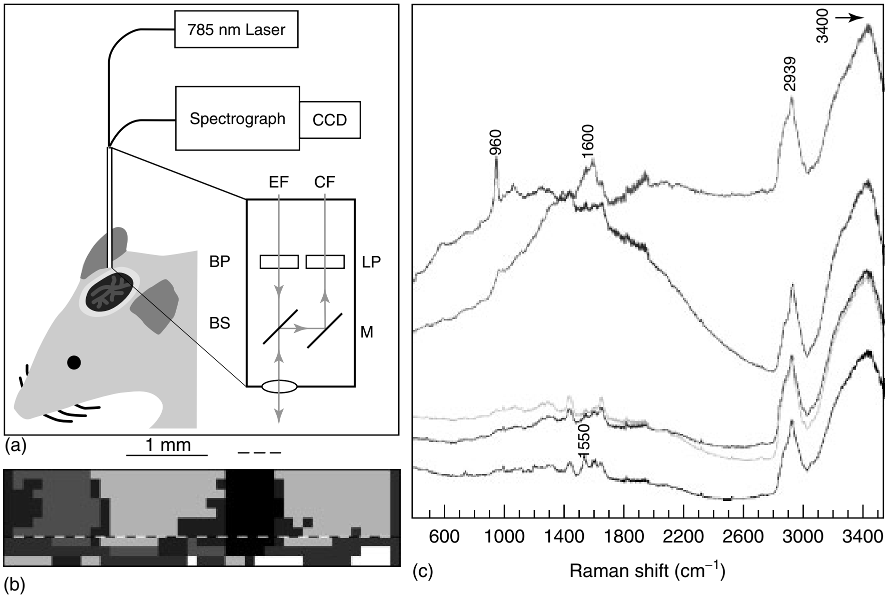

Fig. 28.3 (a) Schematic diagram of the Raman instrumentation: Radiation from a 785 nm laser is coupled into a fiber-optic probe. The scattered radiation is guided to the spectrograph and registered by a CCD detector. The filtered fiber-optic probe consists of an excitation fiber (EF), band pass (BP) filter, beam splitter (BS), lens (L), mirror (M), long pass (LP) filter, and collection fiber (CF). (b) Cluster analysis of 41×10 Raman map. (c) Unprocessed Raman spectra from 400 to 3550 cm^{-1} representing the average of each cluster. Color code: normal brain tissue (blue/cyan), oxygenated blood (black), bone (brown), and brain metastasis of malignant melanoma (red). (Please find a color version of this figure on the color plates.)

of hydroxyapatite of bone. The band at 1550 cm^{-1} belongs to a set of bands characteristic of oxygenized hemoglobin (Wood and McNaughton, 2007). Raman spectra of normal brain tissue are dominated by spectral contributions of lipids and proteins. Although the probe used in this study was too large for endoscopic applications, porcine brain tissue was recently characterized using a single, unfiltered fiber-optic probe (Koljenovic *et al.*, 2007). Instead of maps, single Raman spectra in the high wavenumber region were obtained of 11–19 anatomical structures in seven pig brains. These studies clearly illustrate the potential that Raman spectroscopy holds as a guidance tool during neurosurgical procedures.

28.3.1.2 Tumors of Epithelial Tissue

Epithelium is the collective term for cover and glandular tissue. It is composed of layers of cells that line the outer and inner surfaces of organs. The superficial layer is used to classify the stratification into simple, which consists of a single layer of cells, and stratified, which consists of more than one layer of cells. Stratified epithelium is usually composed of three layers. Cell division takes place in the basal cell layer (layer 1). Cells migrate and differentiate in the intermediate cell layer (layer 2) until they reach the superficial cell layer (layer 3). As the epithelium covers the surface of organs, it is exposed to the environment and is in contact to a broad range of potentially aggressive or harmful chemical and physical conditions that can induce a deregulation of cells' division in the basal cell layer. Therefore, tumors of the epithelium – usually called *carcinomas* – are the most common forms of cancer. Raman studies included carcinomas of the gastrointestinal tract, breast, lung, the urinary tract, cervix uteri, and skin (Section 28.3.4).

Gastrointestinal Tract: Oral Tissue, Esophagus, Intestinal Tissue The Raman and IR fingerprints of normal colon tissue and their distribution in control samples were previously compared in detail (Krafft *et al.*, 2008a). This sample served as a model for the analysis of soft tissue because it contains all four major tissue types such as muscle tissue, connective tissue, epithelium, and also nerve cells. The compilation of these data is important before the methods can be applied to pathological colon tissue such as colorectal adenocarcinoma, which is the third most common form of cancer and the second leading cause of death among cancers in the Western world. Colorectal adenocarcinomas originate from epithelial cells and are able to infiltrate the subjacent layer of colon and rectum. Figure 28.4a and b shows a photomicrograph and the cluster analysis of a 39 × 71 Raman map of an unstained mucosa section. Mucosa is the innermost, highly specialized layer of the gastrointestinal tract that is responsible for absorption and secretion. The Raman map was segmented into clusters of mucus at the top (pink, magenta, violet), submucosa (red), and muscularis

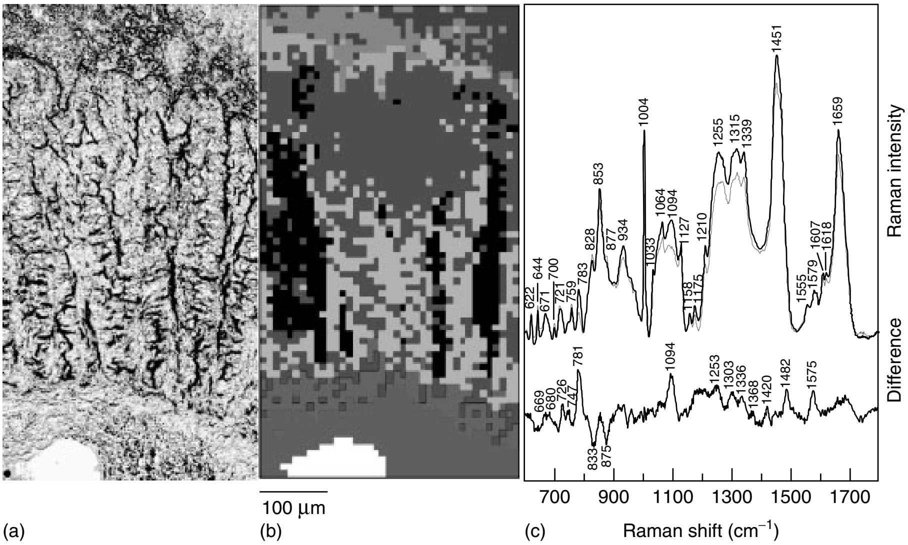

Fig. 28.4 (a) Photomicrograph and (b) cluster analysis of Raman map of mucosa in a colon tissue section. Raman spectra from 600 to 1800 cm^{-1} representing epithelial tissue (cyan cluster, black trace), glandular tissue (black cluster, gray trace), and difference spectrum = epithelial – glandular tissue. (Please find a color version of this figure on the color plates.)

mucusae (olive) at the bottom. The black cluster correlates with glandular features within epithelial tissue (blue/cyan). The segmentation seems to be affected by noise as evident by some heterogeneity in the cluster separation. The Raman spectra representing glands (black cluster) and epithelium (cyan cluster) are overlaid in Figure 28.4c. Although intensity differences in DNA bands at 783, 1094, and 1579 cm^{-1} are visible upon direct comparison, more subtle changes can be inspected in the difference spectrum. Before calculating the difference spectrum, both spectra were scaled to minimize differences in protein bands at 1004, 1451, and 1659 cm^{-1}. All positive difference bands coincide with DNA bands in spectrum 1G of Figure 28.1. The intensity of the DNA bands in the Raman spectra can be correlated with the grade of divisional activity. The mucosal epithelium of the gastrointestinal tract contains epithelial cells that undergo a continual turnover and renewal, and that has a higher proliferation rate than other colonic cells. This property makes these cells susceptible for tumor genesis. Negative difference bands at 833 and 875 cm^{-1} that are hardly visible in the overlaid spectra are associated with the production of mucus in glands.

The feasibility of fiber-optic coupled Raman spectroscopy for disease classification was demonstrated during *in vivo* gastrointestinal endoscopy (Shim *et al.*, 2000). The fiber-optic probe was passed through the endoscope instrument channel, placed in contact with the tissue surface, and spectra could be obtained in 5 seconds. The same instrument was also applied to differentiate adenomatous from hyperplastic polyps in the colon (Molckovsky *et al.*, 2003). A small endoscope system equipped with a micro-Raman probe was developed for *in vivo* Raman measurements of the esophagus and stomach in living rats (Hattori *et al.*, 2007).

Dysplasia is a term used in pathology to refer to an abnormality in maturation of cells within a tissue. It is often indicative for an early neoplastic process. The detection of dysplasia and early cancer is important because of the improved survival rates associated with an early treatment. Dysplasia was induced in the palate of rats by topical application of a carcinogen. Raman spectra were collected *in vivo* by a fiber-optic probe coupled to a Raman spectrometer with an NIR excitation laser (Bakker Schut *et al.*, 2000). Integration time was 100 seconds to record spectra for classification models. These models were trained to distinguish normal-, low-, and high-grade dysplastic tissue. Using signal collection times of 10 seconds, an independent set of spectra was obtained to test the classification models.

Long periods of exposure to gastroesophageal reflux can lead to a change in the lining of esophagus, whereby the normal squamous epithelial lining is replaced by protective columnar epithelial cells. This is termed *Barrett's esophagus* and is associated with an increased risk of developing esophageal adenocarcinoma. Patients with Barrett's esophagus undergo periodic endoscopic surveillance with multiple biopsy examinations in an attempt to differentiate inflammation from dysplastic and early cancerous lesions at a time when intervention can be beneficial. However, this surveillance approach is hindered by low sampling yield, random sampling error, pathology-associated costs, and delay in diagnosis. Fiber-optic Raman spectroscopy was recognized to enhance lesion detection in premalignant conditions. A Raman study of 89 esophageal samples from 44 patients was reported (Kendall *et al.*, 2003; Stone, Kendall and Barr, 2008; Stone *et al.*, 2002). Other normal and abnormal epithelial tissues from the larynx, tonsil, stomach, bladder, and prostate were included in these *ex vivo* investigations. Comparison of prediction of Raman spectral classification models with pathology gave sensitivities of 73–100% and specificities of 90–100%. Another *ex vivo* study collected Raman images to analyze tissue sections from 29 esophageal biopsies (Shetty *et al.*, 2006). Pathologists reviewed contiguous histopathologically stained tissue sections. Objective was to study the biochemical changes that distinguish the different stages of the disease Barrett's esophagus. Raman spectra of the rat esophagus were collected *ex vivo* with three different fiber-optic probes in order to mimic instrument calibration, probe-to-probe and day-to-day variations (Boere *et al.*, 2003). Barrett's and normal epithelium could be discriminated with accuracy higher than 93%.

Lung Tissue Lung cancer is the second most common cancer in humans and the most common cause of cancer deaths in the world. A Raman study of bronchial tissue investigated 28 specimens (Huang *et al.*, 2003) using a Raman spectrometer with 785 nm excitation coupled to a fiber-optic probe, which was developed earlier for skin studies (Huang *et al.*, 2001). Raman spectra were collected with 5 seconds exposure time and the spectral differences between normal and neoplastic tissues were analyzed. Another experimental approach using 1064 nm excitation, a fiber-optic probe, and a newly developed multichannel detector was presented to measure Raman spectra of seven lung tissue specimens (Kaminaka *et al.*, 2002). The data obtained with 400 seconds exposure time distinguished normal and cancerous tissue and also two different types of lung carcinomas. Characterization of the biochemical composition of normal bronchial tissue is important to understand the biochemical changes that accompany lung cancer development. Frozen sections of normal bronchial tissue were studied by Raman imaging (Koljenovic *et al.*, 2004). Subsequent comparison of Raman images with histologic evaluation of stained sections enabled to identify the spectral features of bronchial mucus, epithelium, fibrocollagenous stroma, smooth muscle, glandular tissue, and cartilage. Raman maps were collected from lung tissue and congenital cystic adenomatoid malformation (CCAM) of two patients and compared with FTIR images (Krafft *et al.*, 2008b). At low lateral resolution, a lower red blood cell content and higher lipid content were found in CCAM than in normal lung tissue. At higher lateral resolution, accumulations of lipids and glycogen were identified in CCAM. The lipid aggregates consist of phosphatidylcholine.

Breast Tissue Worldwide, breast cancer is the most common cancer amongst women, with an incidence rate more than twice that of colorectal cancer and cervical cancer and about three times that of lung cancer. Therefore, Raman spectroscopy was applied to complement the existing diagnostic tools. Raman mapping assessed the chemical composition and morphology of breast tissue (Shafer-Peltier *et al.*, 2002) and lymph nodes in tissue sections of breast cancer patients (Smith *et al.*, 2003). Shafer-Peltier (2002) presented a model, which fits macroscopic tissue spectra with a linear combination of basis spectra derived from spectra of the cell cytoplasm, cell nucleus, fat, β carotene, collagen, calcium hydroxyapatite, calcium oxalate dihydrate, cholesterol-like lipid deposits and water. Raman fiber-optical probes are under development to classify normal breast tissue, benign disease, and malignant breast cancer *in vivo* during breast lumpectomy surgeries (Motz *et al.*, 2005). The instrument is capable of collecting and processing Raman spectra in less than 2 seconds. Previous research showed the ability of Raman spectroscopy to accurately diagnose normal, benign, and malignant lesions of the breast *in vivo* in a laboratory setting with high sensitivities and specificities (Haka *et al.*, 2005). Raman spectra were also collected *in vivo* during partial mastectomy breast surgery (Haka *et al.*, 2006) using the previously developed fiber-optical instrument (Motz *et al.*, 2005). Kerr-gated Raman spectroscopy enables to non-destructively probe calcifications buried within breast tissue (Baker *et al.*, 2007). The method used a picosecond-pulsed laser combined with a fast temporal gating of Raman scattered light to collect spectra from a specific depth within scattering media. Spectra characteristic of both hydroxyapatite and calcium oxalate were obtained at depth up to 0.96 mm. As calcium oxalate is associated with benign lesions and hydroxyapatite is found mainly in proliferative lesions including carcinoma, the detection of calcification can indicate the disease state. Typical Raman spectra are already shown in Figure 28.2. Earlier, microcalcifications in benign and malignant breast lesions and their chemical composition were probed by conventional Raman microscopic spectroscopy (Haka *et al.*, 2002).

Urinary Tract: Prostate, Bladder Prostate tissue is structurally complex, consisting primarily of glandular ducts lined by epithelial cells and supported by heterogeneous stroma, and containing also blood vessels, blood, nerves, ganglion cells, lymphocytes, and stones. Benign prostatic hyperplasia is one of the most common diseases in elderly men. It describes an overgrowth of the epithelial and fibromuscular tissues in the human prostate, in which both epithelium and stroma continue to proliferate at different rates. Twenty-nine bladder samples and 38 prostate samples were studied *in vitro* by a Raman system coupled to a fiber-optic probe (Crow *et al.*, 2005). The spectra were correlated with the histologic features and used to develop classifications models. The bladder algorithm was able to differentiate benign samples (e.g. normal and cystitis) from malignant samples (e.g. transitional cell carcinoma). The prostate algorithm was able to differentiate benign samples (e.g. prostatic hyperplasia and prostatitis) from malignant samples (prostate cancer). Kerr-gated Raman spectroscopy uses a picosecond-pulsed laser as well as fast temporal gating of collected Raman scattered light. This technique suppresses signals from both surface and deep layers in bladder and prostate tissue and enables collecting Raman spectra from different depths (Prieto *et al.*, 2005). Another new approach used high wavenumber Raman microspectroscopy to image bladder tissue sections (Koljenovic *et al.*, 2005b). Raman spectroscopy was applied to discriminate between nontumor and tumor bladder tissue sections from 15 patients and to determine the biochemical differences therein (de Jong *et al.*, 2006).

Cervix Uteri Cervical cancer is malignant cancer of the cervix uteri. According to the WHO (fact sheet 297: cancer), cervical cancer is the fifth most deadly cancer in woman. While FTIR spectroscopy was mainly applied to screen cell specimens collected during Pap smear tests, focus of the Raman spectroscopic research on cervical tissue was *in vivo* assessment of squamous dysplasia by fiber-optic probes (Mahadevan-Jansen *et al.*, 1998; Utzinger *et al.*, 2001). The first study reported the design and testing of a fiber-optical Raman system, whereas the second study presented the results of a pilot clinical trial at three clinical sites. Raman spectra were measured from one colposcopically normal and one abnormal area of the cervix in 13 patients. Comparison to histologic analysis revealed that the spectral data were able to identify high-grade squamous dysplasia, misclassifying only one sample.

28.3.2
Mineralized Tissue

Raman spectroscopy has been used for several years to characterize mineralized structures in living organisms, notably bone, teeth, and calculus. Calculus is the collective term for a stone that forms in an organ or duct of the body. The application of vibrational spectroscopy to the study of mineralized tissue was reviewed (Carden and Morris, 2000). Mineralized biological samples are composed of an inorganic matrix (calciumphosphate) and an organic matrix. With the application of Raman imaging spectrometers to mineralized biological samples, spatial variations of the mineral content, mineral crystallinity, and the content/nature of the organic matrix consisting predominantly of collagen type 1 and cells are obtained. The spectral data can monitor the extent of mineral formation in tissue using a mineral to protein ratio. Other parameters monitor the size and perfection of the crystals and the ratio of carbonate ions and phosphate ions in the hydroxyapatite lattice. Furthermore, the interactions between prosthetic implants and tissue can be characterized.

28.3.2.1 Bone

The structural properties of bone were examined by Raman imaging at 785 nm excitation with micrometer range spatial resolution (Carden *et al.*, 2003; Timlin *et al.*, 1999). In contrast to conventional histological techniques, Raman spectroscopic methods do not require a special sample preparation, for example, homogenization, decalcification, extraction, or dilution. They enable to investigate hard tissue under native conditions. Recently, Raman images from bone were also collected at 532 nm excitation after the fluorescence background was reduced by photochemical bleaching (Golcuk *et al.*, 2006). Advantages of the shorter excitation wavelength are higher quantum efficiency of CCD detectors and more intense Raman signals due to the fourth power dependence of scattering intensity with excitation frequency. Both effects result in shorter acquisition times. Typically, Raman images of $300 \times 100\ \mu m^2$ areas with 2 μm resolution just require 10 minutes. The first transcutaneous Raman spectrum of human bone *in vivo* has been obtained at skin-safe laser illumination levels using SORS (Matousek *et al.*, 2006). This technique, which is based on collecting Raman spectra away from the point of laser illumination using concentric rings of optical fibers, provides chemically specific information on deep layers of human tissue well beyond the reach of existing comparative approaches. Raman imaging studies of bone-related diseases include craniosynostosis, which is an abnormal condition of bones making up the skull (Crane *et al.*, 2005; Tarnowski *et al.*, 2004). Microdamages in bone that were induced using a cyclic fatigue loading regime were investigated by Raman imaging (Timlin *et al.*, 2000). The bone chemical structure response to mechanical stress was studied by high-pressure Raman spectroscopy (de Carmejane *et al.*, 2005). The results enabled a deeper understanding of the response of tissue to mechanical stress and demonstrated that individual mineral and matrix constituents respond differently to pressure.

28.3.2.2 **Teeth**

In the context of dentistry, Raman imaging studies analyzed the chemical composition of the enamel/adhesive resin interface (Miyazaki *et al.*, 2003), the monomer/mineral distribution in intertubular region of adhesive/dentin interfaces (Wang, Spencer and Yao, 2006) and the adhesive/caries-affected dentin interface (Wang, Spencer and Walker, 2007). Dental resin composites cured with different light sources (Conti *et al.*, 2005), the post-polymerization shrinkage in dental resins (Truffier-Boutry *et al.*, 2006), and natural and deproteinated tooth enamel and dentin (Fattibene *et al.*, 2005) were studied. Another interesting application of Raman spectroscopy is the detection of dental caries in teeth. While OCT was used to screen carious sites and to determine lesion depth, fiber-optical Raman spectroscopy provided biochemical confirmation of caries (Ko *et al.*, 2005). OCT imaging of tooth samples demonstrated increased light backscattering intensity at sites of suspicious carious lesions as compared to the sound enamel. Furthermore, sound tooth enamel exhibited strong Raman polarization anisotropy, whereas early caries consistently showed a lower degree of Raman polarization anisotropy. Raman spectroscopy was also applied to assess how IR laser photobiomodulation improves the quality of healing bone around dental implants in rabbits (Lopes *et al.*, 2007).

28.3.2.3 **Calculi**

A calculus consists of a concretion of material, usually mineral salts. Stones cause various benign and malignant conditions that include nephrolithiasis (kidney stones), cholelithiasis (gallstones), and testicular microlithiasis. The Raman spectroscopic investigation is direct, fast, and nondestructive, and does not require tedious sample preparation. There are at least two Raman-based approaches to the quantitative analysis of the stone composition. Partial least squares (PLS) techniques will yield highly precise results if the composition of the unknown material is restricted to a reasonably well-defined range, with predictable components present. Another approach is based on supervised methods or on library searching. An unknown sample spectrum is then compared to a number of well-assigned library spectra and the best correlated spectrum is found. In particular, Raman spectroscopy is well suited to detect phosphate-type kidney stones because the main constituent hydroxyapatite has a distinctive line at 961 cm^{-1} which can be used as a "marker" band. The Raman and IR spectra of calculi have previously been summarized (Nguyen and Daudon, 1997).

Kidney Stones Approximately 5% of the population will suffer from kidney stones at some point in their life. About 70% of all kidney stones are composed of calcium oxalate, and small amounts of calcium hydroxyapatite, uric acid, and magnesium ammonium phosphate. Other types of stones consist of 50% hydroxyapatite or calcium monohydrogen phosphate or are composed of cystine. Raman spectroscopic studies on kidney stones demonstrated that vibrational spectroscopy deliver useful information on the stones' structure and composition. Raman spectra of standard phosphate compounds were obtained and applied to the analysis of phosphate-type kidney stones (Kodati *et al.*, 1991). Monohydrate and dihydrate forms of oxalate inclusions were differentiated in tissue section (Pestaner *et al.*, 1996). The detection of struvite in urinary stones was compared between Raman and IR spectroscopy (Takasaki, 1996).

Gallstones Ten to fifteen percent of the population carries gallstones that stay asymptomatic in most cases (ca. 75%). Gallstones are commonly classified into three classes: cholesterol (white), pigment (black), and mixed (brown) stones. Each type of stones has its own treatment regimens. Determination of composition is one fundamental part in establishing the cause and likelihood of recurrence of stones, as well as an appropriate treatment. Raman spectroscopy was used as an analytical technique to determine the structural composition of gallstones from 40 patients (Paluszkiewicz *et al.*, 1998). The utilization of Raman microscopic techniques permitted to map the distribution of the gallstone components leading to identification and characterization of the site of nucleation (Vitetta, Best and Sali, 2000). Polymorph modifications of calcium carbonate in gallstones were investigated using X-ray powder diffraction and spectroscopic techniques including Raman spectroscopy (Palchik and Moroz, 2005).

Testicular Microliths Testicular microlithiasis is associated with various benign and malignant conditions. However, the molecular constitution of these microliths is largely unknown. Microliths in six samples were investigated by Raman imaging in order to identify their molecular constitution (de Jong *et al.*, 2004). The results showed that microliths are composed of pure hydroxyapatite and that glycogen deposits surround all microliths in the samples associated with germ cell neoplasms but not in the benign case.

28.3.3
Skin

According to a review (Krafft and Sergo, 2006), Raman spectroscopic applications to skin had the highest frequency from 1996 to 2006 in the biomedical field, probably because it is the largest human organ and its surface location makes it easily accessible. Applications to corneocyte biology, pharmacology, and disease diagnosis have been reported. Human skin can be considered as a multilayered system, which is divided into the stratum corneum, the epidermis, and the dermis. The stratum corneum is theskin's outermost layer and the main protective barrier against water loss, microorganisms, and toxic agents. This thin (10–20 μm) superficial region has a biphasic structure consisting of anucleated, keratin-rich corneocytes embedded in a highly ordered, lamellar lipid network of ceramides, fatty acids, and cholesterol. A major function of the underlying epidermis is to generate the stratum corneum. The principle cell of the epidermis is the keratinocyte, which differentiates as it migrates toward the stratum corneum. Terminally differentiated keratinocytes generate corneocytes. During differentiation of keratinocytes to corneocytes, a large insoluble protein called *profilaggrin* is converted to filaggrin. Processing of filaggrin includes proteolysis of the protein into its constituents – amino acids, amino acids derivatives, and salts. The resulting mixture, known as *natural moisturizing factor* (*NMF*), provides sufficient hydration to help keep the skin flexible and to facilitate various enzymatic reactions in the pathway that terminates with corneocytes desquamation. The thickness of the epidermis ranges from 40 μm on the eyelid to >1 mm on the palms. The dermis (0.4–4 mm thick) is the underlying layer of the epidermis. The dermis consists of tough connective tissue along with specialized structures. Collagen comprises approximately 75% of the dry weight of the dermis.

28.3.3.1 Corneocyte Biology and Pharmacology

Combined approaches of Raman imaging with FTIR imaging studied the permeation of lipids into skin (Xiao *et al.*, 2005a, 2005b) and the structure during corneocyte maturation (Zhang *et al.*, 2006). Confocal Raman microspectroscopy was applied to the stratum corneum to identify variations in keratin-containing areas (Xiao *et al.*, 2004) and to obtain depth profiles of molecular concentration gradients and transdermal drug delivery up to 200 μm (Caspers *et al.*, 2001). The setup was applied as a noninvasive *in vivo* optical method to determine water concentration profiles of the stratum corneum and to determine changes therein as a result of hydration of the skin (Caspers *et al.*, 2000). Its combination with the imaging modality confocal scanning laser microscopy provides optical sections of the skin without physically dissecting the tissue (Caspers *et al.*, 2003). Natural variations and reproducibility of Raman spectra of normal human skin was studied by a fiber-optic FT-Raman spectrometer (Knudsen *et al.*, 2002). However, exposure times of 8 minutes were reported with this technique, which is much longer than the exposure times for dispersive NIR Raman systems of 30 seconds for the low wavenumber region and 3 seconds for the high wavenumber region (Caspers *et al.*, 2001).

28.3.3.2 Skin Cancer

Skin cancers that include squamous cell carcinoma, malignant melanoma, and basal cell carcinoma (BCC) are the cancers with the highest incidence worldwide. Understanding the molecular, cellular, and tissue changes that occur during skin carcinogenesis is central to cancer research in dermatology. As for many other tissues, vibrational spectroscopy has been used to evaluate these changes (review: (Eikje, Aizawa and Ozaki, 2005)). BCC is the most common cancer of the skin. Raman images were acquired from 15 sections of BCC and compared with histopathology (Nijssen *et al.*, 2002). In this sample set, 100% sensitivity and 93% selectivity were demonstrated. Melanoma is the most aggressive skin cancer and is invariably fatal if left untreated. Clinical diagnostic sensitivity is in the order of 80% for trained dermatologist and much worse for untrained medical personnel. Melanoma removal at an early stage is almost always curative leading to a good prognosis for the patient. Melanoma, pigmented nevi, BCC, seborrheic keratoses, and normal skin were studied by Raman spectroscopy (Gniadecka *et al.*, 2004). The sensitivity and specificity of an artificial neural network classification for diagnosis of melanoma were 85% and 99%, respectively. Recently, it was demonstrated that micro-Raman imaging is also well suitable to distinguish between normal and malignant skin cells at a subcellular level (Short *et al.*, 2006). The Raman scattering was excited at 633 and 515 nm. An excitation power of less than 2 mW ensured that cells were not damaged.

28.3.3.3 **Raman Instrumentation for Skin Studies**

The potential of Raman spectroscopy as a tool for skin studies is now being realized by two commercially available Raman systems. A third Raman system has recently been introduced (Lieber and Mahadevan-Jansen, 2007). A first Raman system was designed, which can be applied noninvasively to record depth concentration profiles of living skin with a resolution of $<5\ \mu m$ (River Diagnostics, Netherlands). Using laser excitation at 671 and 785 nm, a custom built detection system and software tools, various parameters of the skin can be analyzed. Owing to the limited penetration of typically 20–40 μm, most studies are restricted to the stratum corneum. Applications include the determination of (i) the hydration of the skin, (ii) the composition of the NMF, and (iii) the penetration of topically applied materials. This technique can be expected to experience growing use by skin scientists in the cosmetics, pharmaceutical, and dermatological research fields.

A second Raman system determines the carotenoid level in skin (Pharmanex, USA). Carotenoids are known to be important in human health. Most of the health benefits of carotenoids are associated with their action as antioxidants, that is, they protect cells and tissues from the effects of free radicals and reactive oxygen species. As carotenoids are not soluble in water, they are transported in blood by low-density lipoproteins (LDLs). An increase in blood carotenoids is reflected in an increase of carotenoid in all the organs in the body, which can take up lipoproteins, including skin. Thus, the direct measurement of carotenoids on skin provides a good indication of the carotenoid concentrations in blood and other tissues and of the body's overall antioxidant status. Owing to the lack of any accepted noninvasive technology for the detection of carotenoids in living human tissue, RRS was applied as a novel and rapid approach (Hata *et al.*, 2000). The Raman signals originating from single bond and double bond stretch vibrations of the π-conjugated carbon backbone of carotenoids at 1159 and 1525 cm^{-1} are enhanced as high as a factor of 100 000 under proper conditions (Koyama, 1995). The instrument uses light emitting diodes (LEDs) that are tuned to 471.3 and 473 nm in place of a laser. Although there is a large native fluorescence level in the skin upon Raman excitation with blue light, carotenoid levels over a large concentration range can be measured.

28.3.4
Atherosclerosis

Atherosclerosis is a disease affecting arterial blood vessels. The atherosclerotic plaque is divided into (i) the atheroma, which is composed of macrophages nearest the lumen of the artery; (ii) underlying areas of cholesterol crystals; and (iii) calcification at the outer base of older and more advanced lesions. Previous research has suggested that the microscopic morphology and chemical composition rather than the anatomy of an atherosclerotic plaque determine plaque stability and disease progression. Developments of compact clinical Raman systems, specially developed Raman catheters and future directions of Raman spectroscopy in cardiovascular medicine were summarized (van de Poll *et al.*, 2002c). The performance of a fiber-optic probe was tested *in vitro* with aorta tissue (Motz *et al.*, 2004). Raman spectra of normal aorta, noncalcified atherosclerotic plaque, and calcified atherosclerotic plaque that were collected in only 1 second with 100 mW excitation could be fitted by model spectra to assess the chemical composition. Another intravascular catheter for Raman spectroscopic detection and analysis of coronary atherosclerotic disease has been developed (Komachi, Sato and Tashiro 2006). The catheter having an outer diameter of 2 mm consisted of a side-view type micro-Raman probe, an imaging fiber bundle, a working channel, and a balloon. By inflating the balloon, the probe was brought close to the inner wall of a modeled blood flow system and detected a phantom target buried in the wall. Raman maps of human atherosclerotic plaques were generated to investigate the chemical composition of the pigment ceroid in cross-sections of the intimal surface (van de Poll *et al.*, 2002a) and to investigate plaque development in mice (van de Poll *et al.*, 2002b). Compact clinical Raman systems and dedicated, miniaturized fiber-optic Raman catheters with a side viewing geometry were used *ex vivo* in human coronary arteries (van de Poll *et al.*, 2003) and *in vivo* in lambs and sheep to illuminate the blood vessel wall and to collect Raman scattered light (Buschmann *et al.*, 2000). The *in vivo* intravascular Raman signal obtained from a blood vessel was found to be a simple summation of signal contributions of the blood vessel wall and of blood. Therefore, algorithms previously developed from single point Raman spectra (Römer *et al.*, 1998) could be adapted to extract information about the chemical composition of blood vessel walls from *in vivo* Raman spectra.

28.3.5
Ophthalmology

Ophthalmology is the branch of medicine, which deals with the diseases and surgery of the visual pathways. Because Raman signals are typically weak, intense lasers in combination with sophisticated light collection are usually used. Although intense laser radiation can potentially harm the delicate structures in the visual system, ocular tissue has been found to be a very suitable target for Raman spectroscopy for two reasons. First, the ocular media (cornea, lens, and vitreous) generally have good optical clarity, which enables high penetration of laser excitation and optical detection of scattered radiation. Secondly, the retina also contains the pigment carotenoid. Owing to its two orders of magnitude higher abundance compared with skin, the excitation intensities can be reduced to light levels that are within established safety ranges. No other biological molecules found in significant concentrations in human ocular tissues exhibit similar resonant enhancement with blue laser excitation so the *in vivo* carotenoid Raman spectra are remarkably free of confounding responses.

28.3.5.1 Macular Degeneration of the Retina

Age-related macular degeneration (AMD) is the leading cause of irreversible blindness in the elderly. Carotenoid macular pigments may provide protection against light-induced oxidative damage and lower the risk for this pathology. To explore the role of carotenoids in modifying the risk of AMD further, clinical studies to quantify their levels in the living human macula are impaired by the lack of appropriate instruments. Raman spectroscopy has been shown to assess the concentration and the spatial distribution of carotenoids in the retina through undilated eyes noninvasively within a fraction of a second (Bernstein *et al.*, 2004). Ocular Raman instruments were designed for this special application (Spectrotek LC, USA). However, the company is no longer in business yet. A new generation of ocular RR scanners will incorporate wide-field imaging of macular carotenoid distributions (Gellermann *et al.*, 2002).

28.3.5.2 Chemical Composition of the Vitreous and the Lens

Imaging vitreous is a quest to view what is, by design, invisible. The combined use of techniques including Raman spectroscopy could provide better imaging of vitreous for future investigational and clinical purposes. Raman spectroscopy was applied to image the vitreous in order to detect altered vitreous molecules such as glycated collagen and other proteins in diabetic vitreopathy (Sebag, 2004). Diabetes mellitus succeeded by diabetic cataract was induced to rats, and eye properties deterioration was monitored from clinical standpoint and by Raman spectroscopy (Furic, Mohacek-Grosev and Hadzija, 2005). The formation of nuclear cataract was induced in guinea pigs with hyperbaric oxygen, and changes in disulfides (S–S) and sulfhydryls (S–H) were measured in isolated lenses by Raman spectroscopy (Gosselin *et al.*, 2007). Using filipin as an external Raman label, which binds specifically to cholesterol, the distribution of cholesterol in a rat eye lens was determined by Raman spectroscopy (Sijtsema *et al.*, 1996). The protein distribution was obtained by using intrinsic Raman protein bands. Calcification of senile cataractous lens was determined by Raman microscopic spectroscopy (Chen *et al.*, 2005).

28.4
Raman Spectroscopy in Clinical Chemistry

28.4.1
Determination of Glucose

A number of common clinical chemistry tests have proven to be feasible using Raman spectroscopy. Among the most important applications is the fast and reliable determination of the blood glucose level of diabetic patients. Normally, glucose level is tightly regulated in human body. Failure to maintain blood glucose in the normal range between 70 and 150 mg dl^{-1} leads to conditions of persistently high (hyperglycemia) or low (hypoglycemia) blood sugar. Diabetes mellitus, which is characterized by persistent hyperglycemia of several causes, is the most prominent disease related to failure of blood sugar regulation. Raman spectroscopy was explored as a reagent-free tool for predicting the concentrations of different parameters in blood serum and serum ultrafiltrate (Rohleder, Kiefer and Petrich, 2004). In an investigation using samples from 247 blood donors, the concentrations of glucose, triglycerides, urea, total protein, cholesterol, high-density lipoprotein (HDL), LDL, and uric acid were determined with accuracy within the clinically interesting range. Furthermore, it was shown that ultrafiltration can efficiently reduce fluorescent light background to improve prediction accuracy such that the relative coefficient of variation decreased for glucose and urea in ultrafiltrate by more than a factor of 2 when compared to serum.

Another approach for the detection of blood glucose level is the application of SERS substrates. The normal Raman cross-section of glucose is rather small and additionally the adsorption of glucose molecules on the surface of SERS substrates made out of silver or gold is weak. Therefore, a direct identification of glucose using SERS is limited. Wu *et al.* (2006) applied a modified analysis system: in a first step glucose was modified by an enzymatic reaction to gluconolacton, which converts *o*-phenylenediamine in an oxidation–condensation to azoaniline. Azoaniline, on the other hand, can easily be detected by SERS spectroscopy. With this approach, a glucose concentration of minimal 0.5 mM could be correctly predicted.

A more direct approach is the use of metal films over nanospheres (FON) as SERS substrates. These substrates were modified with a partition layer in which glucose can penetrate. This enables then to monitor the glucose SERS signals in combination with the SERS signals of the partition layer. Yonzon *et al.* (2004) used Cu FON to monitor glucose concentration in the presence of bovine serum albumin to simulate blood environment.

Stuart *et al.* (2005) used both Au and Ag FON in order to monitor the time stability of the SERS substrate for the detection of glucose. Lyandres *et al.* (2005) used Ag FON in combination with a mixed decanethiol (DT)/mercaptohexanol (MH) partition layer to improve the detection level.

Beside the classical analysis of the glucose levels in blood, the correlation of blood with other body fluids can be used to measure noninvasively. One possibility is the aqueous humor in the anterior chamber of the eye. Since the aqueous humor is an ultrafiltrate of the blood, its glucose level correlates with the blood glucose level. Pelletier, Lambert, and Borchert (2005) investigated human aqueous humor samples collected from cataract surgeries as well as artificial aqueous humor samples as a model system. With this model, they could show that a model out of glucose and different other substances such as lactate or urea could be used to predict the glucose level of human aqueous humor *in vitro*. Lambert, Pelletier, and Borchert (2005) tested this assumption on the anterior chamber of rabbits and could predict the blood glucose level without damaging the retina. Sideroudi *et al.* (2007) measured the concentrations of antibiotics, for example, ciprofloxacine, in an artificial anterior chamber.

28.4.2
Serum Analysis

Beside the status of blood cells, also the composition of the serum reveals information about the health condition. Qi and Berger (2007) investigated serum samples with a liquid core optical fiber (LCOF). In this study 71 blood serum and 61 urine samples were investigated with NIR excitation in combination with PLS analyzing the concentration of 13 chemicals, for example bilirubine, cholesterol HDL and LDL at the same time. Rohleder *et al.* (2005) analyzed serum and serum ultrafiltrate samples from 247 blood donors to predict the concentration of, for example, glucose, triglycerides, HDL, and LDL with an accuracy within the clinical interesting range.

Harz *et al.* studied cryoprecipitated plasma samples by means of UV-resonance Raman spectroscopy. With this method, the increase of von Willebrand Factor multimers can be identified in samples from diseased persons enabling for early detection of microangiopathy (Harz *et al.*, 2006).

28.4.3
Malaria Investigations

Malaria is one of the most common infectious diseases and an enormous public health problem. The disease is caused by protozoan parasites of the genus Plasmodium. The parasites multiply within red blood cells, also known as *erythrocytes*, where they digest a major proportion of red cell hemoglobin. As free heme (ferriprotoporphyrin IX), a product of hemoglobin digestion, is toxic for the parasite it detoxifies free heme by conversion into an insoluble crystal called *hemozoin* or *malaria pigment*. The early detection of parasite infection is vital to the application of an early and appropriate therapy. Especially, malaria is a disease where the mode of action of the applied pharmaceuticals is not fully understood. Using resonance Raman spectroscopy, the characterization of hemozoin under different physiological conditions (Frosch *et al.*, 2007b) as well as the influences of quinoline additives (Solomonov *et al.*, 2007) or chloroquine (Frosch *et al.*, 2004) of β-hematin crystals can be investigated. The synthetic compound β-hematin is a structural analog of hemozoin.

Comparison of resonance Raman spectra of β-hematin, normal erythrocytes, parasite-infected erythrocytes, and lysed samples of the parasite-infected erythrocytes at different wavelengths enables for the clear distinction between normal and infected erythrocytes (Ong *et al.*, 2002). The characterization of hemozoin and hemoglobin inside the food vacuole of *Plasmodium falciparum* and β-hematin as well as the monomer hematin shows the identical Raman spectra of hemozoin and β-hematin with an exceptionally strong marker band at 1374 cm^{-1} (Frosch *et al.*, 2007a; Wood *et al.*, 2003). Using micro-Raman spectroscopy, the structural changes of hemozoin in *P. falciparum* during chloroquine exposure can be monitored (Webster *et al.*, 2008). Raman acoustic levitation spectroscopy (RALS) of lysed red blood cells allows for the faster detection of malaria infection inside 10 µl droplet (Puskar *et al.*, 2007).

28.4.4
Analysis of Hair and Nails

For forensic application, Widjaja and Seah Regina Kim (2006) were able to differentiate between Raman spectra of fingernails and toenails using NIR excitation. Beside nails, hair is a good reservoir for accumulated chemicals over time as well as a possibility to investigate physiological changes with minimal invasive effort. Trichothiodystrophy (TTD), for example, is a disease induced by a reduced content of cystine in the proteins, where the hair breaks very easily. Osada *et al.* studied the molecular change in the hair protein during TTD. Patients with TTD exhibit hair with altered disulfide bonds. Here, the Raman signals were shifted to higher wavenumber region indicating a change toward a *gauche–gauche–trans* conformation in the TTD hair (Osada *et al.*, 2003). Normal hair shafts and hair shafts from patients exhibiting TTD were compared by Raman line scanning over the hair (Schlücker *et al.*, 2006) or by Raman point measurement (Liang *et al.*, 2006). Both studies found conformational change of the disulfide bonds and correlated this to the hair brittleness.

28.5
Conclusions and Outlook

The increased interest in Raman spectroscopy for applications in medicine and life science is clearly demonstrated by recent book publications. A book entitled "Vibrational Spectroscopy in Life Science" described Raman and IR spectroscopy of specific biological systems, such as proteins and membranes (Siebert and Hildebrandt, 2007). Another book entitled "Vibrational Spectroscopy for Medical Diagnosis" summarized various biomedical applications including pathology, clinical chemistry, detection of cancer, and identification of pathogenic microorganisms (Diem, Griffiths and Chalmers, 2008). The forthcoming book "Infrared and Raman Spectroscopic Imaging" focuses on imaging applications in biology and medicine as well as in chemical, pharmaceutical, and food industries (Salzer and Siesler, 2009). According to a recent review (Krafft and Sergo, 2006), IR spectroscopy was applied two times more frequently from 1996 to 2006 than Raman spectroscopy to tissue diagnosis. Although single Raman spectra can be acquired in seconds, acquisition of Raman images that consist of thousands of spectra is usually more time consuming and the signal-to-noise ratio is inferior compared with FTIR imaging. Nevertheless, Raman imaging offers advantages in terms of (i) studying nondried specimens, (ii) the maximum, diffraction limited lateral resolution is higher, (iii) the spectral range can easily be extended to lower wavenumbers, (iv) the technique can be coupled to fiber-optic probes, and (v) enhancement effects can be utilized. For example, the RR effect was used for rapid and sensitive detection of carotenoids in skin

(Hata *et al.*, 2000) and retina (Bernstein *et al.*, 2004), the malaria pigment hemozoin in erythrocytes (Frosch *et al.*, 2007b), and melanin in brain metastases of malignant melanomas (Krafft *et al.*, 2007). Using nonlinear Raman effects such as coherent anti-Stokes Raman spectroscopy (CARS) signal intensities can also be enhanced by several orders of magnitude. CARS is a four-photon process, which uses two picosecond-pulsed laser for excitation under a defined geometry. Owing to the intense signals, CARS in combination with fast scanning mirrors offers an attractive perspective to reduce the acquisition time of Raman images. CARS imaging with video rate microscopy of skin tissue in a live mouse (Evans *et al.*, 2005) and brain structures (Evans *et al.*, 2007) at subcellular resolution has already successfully been performed. With the ongoing progress in light sources, optical components, detectors, and algorithms for data processing, the number of Raman spectroscopic applications in medicine will increase in the future. Although in its early stages, one can be optimistic that Raman spectroscopy has the potential to be fully accepted as a diagnostic tool with sufficient sensitivity and specificity for rapid and nondestructive *in vitro, ex vivo*, and *in vivo* analyses.

3.1
Introduction

Mössbauer spectroscopy is a unique technique based on the nuclear resonance via recoil-free emission, absorption, and scattering of γ-rays. Because of its extremely high energy resolution and its particular timescale, a Mössbauer spectrum can provide valuable information on structural, chemical, magnetic, and dynamic properties of a variety of solid materials. Mössbauer spectroscopy finds applications in various fields of scientific research, such as physics, metallurgy, materials science, chemistry, mineralogy, biology, medicine, environmental science, archeology, and art. In this chapter, the theoretical principles, experimental techniques, and various applications of Mössbauer spectroscopy are briefly described. For rigorous theoretical treatment and complete experimental details, the reader is referred to specialized books and review articles listed in the Further Reading section at the end of this chapter. There are more than 50 000 journal articles reporting research using Mössbauer spectroscopy in the literature. They have been systematically collected by the Mössbauer Effect Data Center at the University of North Carolina at Asheville and compiled in the Center's publications *The Mössbauer Effect Data Index* (1966–77) and *The Mössbauer Effect Reference and Data Journal* (since 1978).

3.2
The Mössbauer Effect

The principle of Mössbauer spectroscopy is based on the recoil-free nuclear γ-resonance, known as the *Mössbauer effect*, named after its discoverer Rudolf L. Mössbauer. γ-Rays are photons emitted from certain nuclei when they make a transition from an excited state to a lower state. These γ-rays may be absorbed by other nuclei of the same isotope in their lower state, making a transition to the same excited state, much like any other resonance absorption phenomenon. This lower state is usually the stable ground state, whereas the excited state has a typical lifetime of $\tau \approx 100$ nanoseconds. According to the uncertainty principle $(\Delta E)(\Delta t) \sim \hbar$, where the Planck constant $\hbar \approx 10^{-15}$ eV s, this lifetime corresponds to a natural linewidth of $\Gamma \approx 10^{-8}$ eV. Since the γ-photon energies are typically in the order of $E_\gamma \approx 10^4$ eV, this linewidth $(\Gamma/E_\gamma \approx 10^{-12})$ is very narrow and characterizes an extremely "monochromatic" nature of

γ-rays emitted from a particular nuclear isotope. We are fortunate to have access to nuclear γ-rays possessing such a unique quality, but this is a double-edged sword. On the one hand, an extraordinarily high energy resolution can be achieved if γ-rays are used in resonance spectroscopy. On the other hand, a precise resonance condition within 10^{-8} eV must be strictly satisfied between the emitter and the absorber.

During the first half of the twentieth century, considerable amount of research was devoted to finding ways of matching the energies of emitted γ-photons with the energy requirement for nuclear resonant absorption. The main obstacle was recoil of the nucleus, during emission as well as absorption of γ-rays. When a free nucleus emits a photon of energy E_γ (Figure 3.1), the photon carries with it a momentum of

$$p = \frac{E_\gamma}{c} \tag{3.1}$$

where c is the speed of light. According to momentum conservation, the nucleus recoils in the opposite direction with the same moment p, which corresponds to a recoil kinetic energy of

$$E_R = \frac{p^2}{2M} \tag{3.2}$$

where M is its mass. Because of this recoil energy, the actual energy of the emitted photon is reduced by E_R, and Eq. (3.2) can be rewritten as

$$E_R = \frac{(E_\gamma/c)^2}{2M} = \frac{E_\gamma^2}{2Mc^2} \tag{3.3}$$

The absorption of a γ-photon by a free nucleus involves exactly the opposite recoil process – the nucleus will gain a momentum of p and a recoil kinetic energy of E_R. Therefore, a photon of merely an energy of E_γ does not suffice to cause a nuclear transition, but an excess energy of E_R is needed to compensate the recoil energy imparting the motion to the nucleus.

Since the rest mass M_ec^2 of an electron is about 0.5 MeV and a typical nucleus is about 10^5 times more massive than the electron, the nuclear rest mass Mc^2 is of the order of 10^{11} eV. Using $E_\gamma \approx 10^4$ eV, we estimate the recoil energy

$$E_R \approx \frac{(10^4)^2}{10^{11}} = 10^{-3}\ \text{eV} \tag{3.4}$$

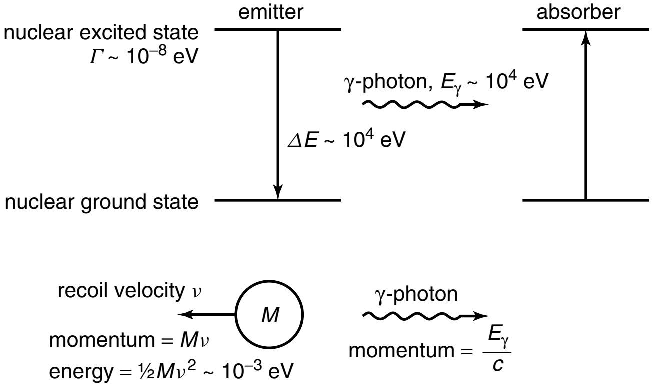

Fig. 3.1 Emission of a γ-photon and recoil of the nucleus.

This is about 100 000 times larger than the natural linewidth Γ of the photon energy; therefore, recoil of a free nucleus shifts the photon energy far beyond its "bandwidth" and completely destroys the resonance condition.

Various methods, mostly based on the Doppler effect, were used to compensate the recoil energy by raising the emitted photon energy so that the emission and absorption lines overlapped, at least partially. For example, it was well known that the Doppler broadening associated with thermal motion of the nuclei could add energy to photons emitted from those fast-moving nuclei that had the same direction as the γ-rays. Alternatively, macroscopic mechanical motion ($\sim 10^5$ cm s^{-1}) of the emitting nuclei (i.e., a source) toward the absorber could shift the photon energy to meet the resonance condition. In certain situations, a preceding nuclear reaction may result in a fast-moving nucleus so that the Doppler shift in the emitted photon could become large enough to cause resonance absorption. These techniques did allow the observation of nuclear resonance, but the recoil energy was merely compensated, often at the expense of the energy resolution and the loss of γ-ray intensity.

Mössbauer (1958) discovered a distinctively new phenomenon that, when the emitting nuclei are bound in a solid, a fraction of the emitted γ-rays have exactly the energy E_γ, corresponding to a recoil-free process. This process seemingly violates the conservation of momentum when we consider one individual emission. However, we should realize that the recoil momentum and energy can no longer be transferred to the emitting nucleus alone, but to a large number of tightly bound atoms within the entire solid, in the form of their simultaneous vibrations (i.e., creating phonons). While using γ-rays from ^{191}Ir and comparing their resonant scatterings by Ir and Pt, Mössbauer experimentally observed higher scattering intensities by Ir at lower temperatures, which contradicted the theory based on thermal broadening of the γ-rays. He then successfully observed higher resonant absorption of the 129 keV radiation from Ir at a temperature of 88 K and correctly attributed the phenomenon to the zero-phonon process (Mössbauer, 1958, 2000). Because the typical phonon frequency is in the order of 10^{13} Hz (corresponding to $\hbar\omega \sim 10^{-2}$ eV), a single recoil ($\sim 10^{-3}$ eV) does not have enough energy to create one phonon (Figure 3.2).

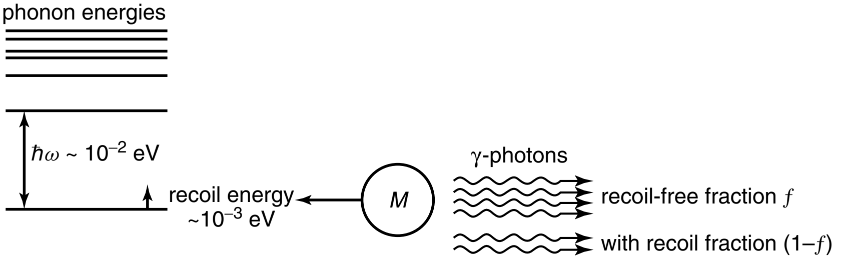

Fig. 3.2 Recoil energy compared with the phonon energy in a typical solid. Because the recoil energy due to the emission of one photon is not large enough to create one phonon, a fraction of photons are emitted in the recoil-free fashion.

Therefore, there is a sizeable probability of recoil-free emission. If all emissions (both recoil-free and with recoil) are considered collectively, momentum and energy conservation laws are completely obeyed.

When these γ-rays, emitted in the recoil-free fashion, are allowed to be absorbed, also in a similar recoil-free way, resonance experiments can be carried out without the need for energy compensation. Now we have essentially two categories of γ-photons; some are emitted, absorbed, or scattered at exactly the energy corresponding to a nuclear transition, and others carry higher or lower energies corresponding to the creation or annihilation of certain phonons. The first group (recoil-free) is wonderfully suitable for resonance experiments with extremely high energy resolution, whereas the second group is suitable for studying lattice dynamics because these γ-rays (with recoil) carry information about phonon distribution in the emitter, absorber, or scatterer. In recognition of his experimental discovery and theoretical interpretation of this recoil-free phenomenon, Mössbauer was awarded the Nobel Prize in physics in 1961 and this phenomenon has since been known as the *Mössbauer effect*.

3.3
The Recoil-Free Fraction

The recoil-free γ-photons constitute a fraction of the total γ-radiation emitted from a particular source. This parameter is known as the *recoil-free fraction* f. The value of f obviously depends on how the recoil energy E_R compares with the phonon energies $\hbar\omega$. Only when $E_R << \hbar\omega$ will f be reasonably large. According to Lipkin's sum rule (Lipkin, 1960), when a large number of absorption events are considered, the average energy transferred to the lattice must be exactly equal to E_R. Let a total of m γ-photons be emitted, among which n are recoil-free and, among the remaining photons, each excites a single phonon (neglecting double phonons). Then

$$mE_R = (m - n)\hbar\omega \tag{3.5}$$

On the basis of the Einstein model of lattice vibrations of a single frequency ω, we arrive at an approximate expression for the recoil-free fraction f:

$$f = \frac{n}{m} = 1 - \frac{E_R}{\hbar\omega} \tag{3.6}$$

A more precise expression for the recoilless fraction is

$$f = e^{-k^2\langle u^2\rangle} \tag{3.7}$$

where $\langle u^2\rangle$ is the mean-square displacement of a nucleus along the direction of the wave vector $\boldsymbol{k}$ of the emitted γ-ray. The wave vector $\boldsymbol{k}$ is related to the photon energy E_γ by $\hbar k = E_\gamma/c$. This expression in Eq. (3.7) points out that to have a relative large f, both the γ-photon energy E_γ and the atomic vibrations $\langle u^2\rangle$ should be small. The first condition of small $\boldsymbol{k}$ can be satisfied by selecting isotopes with low-energy γ-transitions. At present, Mössbauer effect has been observed from more than 100 nuclear isotopes (e.g., ^{57}Fe, ^{119}Sn, ^{191}Ir, etc.), many of which have transition energies less than 50 keV. The second condition of small $\langle u^2\rangle$ requires a rigidly bound solid (characterized by a high Einstein or Debye temperature), perhaps cooled to a low temperature (small vibration amplitudes). This implies that in a liquid or a gas, Mössbauer effect is extremely difficult to observe because of the large $\langle u^2\rangle$ values. For any γ-ray energy higher than 100 keV, the source and the absorber are usually kept at low temperatures to reduce their $\langle u^2\rangle$ values.

The mean-square displacement $\langle u^2\rangle$ is intimately related to lattice dynamics, that is, how the collective atomic vibrations take place at a given temperature. We adopt a particular model for lattice dynamics, for example, the Debye model with a phonon density of states (DOS) $g(\omega) = 3\omega^2/{\omega_D}^3$, where ω_D is related to the parameter known as the *Debye temperature* θ_D through the Planck and Boltzmann constants, $\hbar\omega_D = k_B\theta_D$. Applying the Bose–Einstein distribution of phonons among the available phonon states at temperature T, we arrive at a more specific expression for the recoil-free fraction,

$$f = \exp\left[-k^2\frac{3\hbar^2}{Mk_B\theta_D}\left(\frac{1}{4}+\frac{T^2}{\theta_D^2}\int_0^{\theta_D/T} \times \frac{xdx}{(e^x-1)}\right)\right] \tag{3.8}$$

where $x = (\hbar\omega)/(k_BT)$ is a dimensionless variable for the definite integral, which covers the range from 0 to θ_D/T. In the high-temperature limit ($\theta_D/T \ll 1$), x only takes small values, $e^x \approx 1 + x$, and the above expression simplifies to

$$\begin{aligned} f &\approx \exp\left[-k^2\frac{3\hbar^2}{Mk_B\theta_D}\left(\frac{1}{4}+\frac{T}{\theta_D}\right)\right] \\ &\approx \exp\left[-k^2\frac{3\hbar^2 T}{Mk_B\theta_D^2}\right] \end{aligned} \tag{3.9}$$

In the low-temperature limit ($\theta_D/T \gg 1$), the integral has a value of $\pi^2/6$, and the above express simplifies to

$$\begin{aligned} f &\approx \exp\left[-k^2\frac{3\hbar^2}{Mk_B\theta_D}\left(\frac{1}{4}+\frac{\pi^2T^2}{6\theta_D^2}\right)\right] \\ &= \exp\left[-k^2\frac{\hbar^2}{2Mk_B\theta_D}\left(\frac{3}{2}+\frac{\pi^2T^2}{\theta_D^2}\right)\right] \end{aligned} \tag{3.10}$$

At absolute zero ($T = 0$ K), it is simply

$$f = \exp\left[-k^2\frac{3\hbar^2}{4Mk_B\theta_D}\right] \tag{3.11}$$

The Debye model assumes isotropic, harmonic vibrations only. When the lattice has lower symmetry, $\langle u^2\rangle$ depends on the atomic vibration direction with respect to the lattice symmetry axes, resulting in an anisotropic behavior of the recoil-free fraction f. This affects the quantitative measurement of Mössbauer effect, which was first observed by Goldanskii in polycrystalline samples (Goldanskii *et al.*, 1962) and was first explained theoretically by Karyagin (Karyagin, 1963). This phenomenon is known as the *Goldanskii–Karyagin* (*G–K*) effect, which can be used to study anisotropy in lattice dynamics. External pressure applied to the solid may also cause a change in the mean-square displacement $\langle u^2\rangle$ and produce additional anisotropy, which will be reflected in a change in the recoil-free fraction. At high temperatures, if the Mössbauer effect still persists, anharmonicity in the atomic vibration may render the Debye model invalid, and the theoretical treatment of f may involve higher order terms and become a complex function of temperature. Even at low temperatures, anharmonic behavior has been detected in several solids.

It is important for resonant absorption experiments that a relatively large

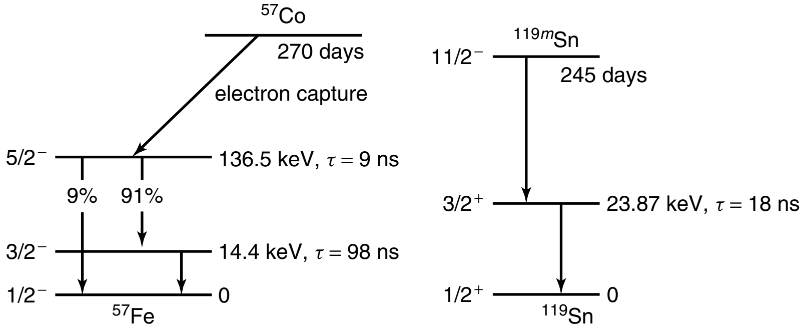

Fig. 3.3 Nuclear decay schemes of ^{57}Co and ^{119m}Sn.

fraction is available and its variation is precisely known (e.g., whether f remains constant when comparing results from a series of samples, or how f changes within the temperature range of the experiments). It is even more important for investigating lattice dynamics using Mössbauer effect because f carries all the information about phonon behavior. Special attention has always been paid to the precise measurement of the recoil-free fraction f. The precision has reached 1% when radioactive sources are used, and it can be better than 0.4% when synchrotron radiation is employed. Very often, we are more interested in how f changes with sample composition, temperature, or pressure than in the absolute value of f.

3.4
Sources of Mössbauer Radiation

Mössbauer effect has been observed in about 100 isotopes. ^{40}K is the lightest isotope, followed by ^{57}Fe. The Mössbauer isotopes are not distributed evenly in the periodic table – about 75% of them are concentrated in elements of atomic numbers between 50 and 80. There are only about 20 Mössbauer isotopes that are in practical use. ^{57}Fe and ^{119}Sn, whose decay schemes are given in Figure 3.3, are the most popular. ^{57}Fe is by far the most important Mössbauer isotope; more than 70% of the research work involves ^{57}Fe. Other frequently used isotopes are ^{151}Eu, ^{197}Au, ^{129}I, ^{121}Sb, and ^{125}Te. Increased attention has been paid to ^{237}Np, ^{155}Gd, ^{161}Dy, and especially to ^{67}Zn and ^{181}Ta, which are used for taking high-resolution spectra.

For ^{57}Fe Mössbauer spectroscopy, the source usually contains the radioactive ^{57}Co, which captures a K-electron and becomes ^{57}Fe at the 136-keV metastable state. It then makes transitions to the ground state, accompanied by γ-ray emissions, among which the 14.4-keV Mössbauer radiation is the most useful. The half-life of the ^{57}Co decay is $T_{1/2} =$ 270 days.

For Mössbauer spectroscopy, the radioactive isotope is embedded in a solid host material (matrix) to form a Mössbauer source. Mössbauer sources are specially prepared via nuclear reactions, and they are commercially available. Sources can also be made by "in-beam" implantation, allowing the use of isotopes with short life times, such as ^{57}Mn ($T_{1/2} = 1.45$ minutes), which decays directly to the 14.4-keV excited state ^{57}Fe (Yoshida *et al.*, 2002).

The quality of a Mössbauer source depends on the properties of the isotope and the selection of the host material. The Mössbauer isotope should satisfy the following criteria:

1. The γ-photon energy E_γ should be in the range 5–150 keV, preferably less than 50 keV. This is because both the recoil-free fraction f and the resonance cross section σ_0 decrease as E_γ increases, especially f, which decreases more rapidly.
2. The desired lifetime τ of the excited state is 1–100 nanoseconds. A long τ corresponds to a narrow natural width Γ_n, and a slight mechanical vibration may destroy the resonance condition. A short τ means that Γ_n may be too large to yield a high-resolution spectrum.
3. The internal conversion coefficient α should be small (<10), to ensure a relatively large probability of available γ-ray emission.
4. It is preferred that the parent nucleus has a long half-life $T_{1/2}$ and allows for easy production of a high activity source.
5. The Mössbauer isotope should not have a high nuclear spin, which would produce complicated spectra and make analysis more difficult.
6. The Mössbauer isotope should have a reasonably large natural abundance. Among the Mössbauer isotopes, ^{57}Fe fulfills the above requirements most satisfactorily, except for its low natural abundance of 2.14%. ^{119}Sn also possesses many good qualities.

A good Mössbauer source requires an appropriate host, a suitable fabrication process, and so on. The following are the main aspects that should be taken into consideration:

1. The radiation from the source should be monochromatic with an energy width as close to the natural width as possible, which requires that the host matrix be a nonmagnetic material of a cubic lattice and of high purity.
2. The host material should have a high Debye temperature to maximize the recoil-free fraction f; metals (and occasionally ionic crystals) of high melting temperatures are usually chosen for the matrix material.
3. The number of stable Mössbauer nuclei in the host material should be minimized to prevent resonant self-absorption.
4. The host material should be made very thin, to reduce the photoelectric effect and Compton scattering caused by the Mössbauer γ-rays.
5. The host should be chemically stable and properly sealed for protection against oxidation, leakage of radioactive material, and so on. For ^{57}Fe, rhodium (Rh) and palladium (Pd) are good hosts, giving an excellent f-value of about 0.78 at room temperature.

In the last two decades, researchers have also been attracted to synchrotron radiation (SR) as a new Mössbauer radiation source. SR provides polarized pulsed radiation of high intensity, high collimation, and narrow beams. The high intensity of the SR source has been utilized for scattering experiments where conventional radiation sources cannot provide adequate results. The pulsed nature of SR radiation is most suitable for measuring time spectra where the entire nuclear ensemble is excited simultaneously and its coherent decay can be observed at different time intervals. One more advantage associated with SR is that γ-rays are naturally polarized, either linearly or circularly, which allow selective absorption and therefore provide additional information. At present, SR Mössbauer radiation can only be produced in large facilities, such as the European Synchrotron Radiation Facility (ESRF) in Grenoble (France), the Advanced Photon Source (APS) in Argonne (USA), and the Super Photon ring (SPring-8) in Hyogo (Japan).

One of the drawbacks of SR radiation is its relatively wide energy distribution. Therefore, it must be collimated and monochromatized before being used in any absorption or scattering experiments. Going through a double-crystal premonochromator Si(111), followed by a high-resolution monochromator based on particular Bragg reflections, the bandwidth can be reduced to the order of milli electronvolts, or even micro electronvolts.

3.5
The Mössbauer Spectrometer

The most common technique for obtaining a Mössbauer spectrum is using a velocity-scanning spectrometer in the transmission geometry, a block diagram of which is shown in Figure 3.4. It consists of a radiation source, an absorber, a detector with its electronic recording system, a wave-form generator, a drive circuit, and a transducer. A beam of γ-rays from a source containing the Mössbauer isotope is directed toward a thin absorber containing the stable nuclei of the same isotope. The transmitted γ-rays are detected by a suitable detector and recorded in a computer system. To obtain a resonance spectrum (i.e., the amount of transmitted γ-rays versus photon energy), the energy of the incoming γ-rays must be modulated

using Doppler effect. In most cases, the source undergoes a mechanical motion with a velocity v toward or away from the absorber, whereas the absorber is at rest, so that it is easier to change its temperature or to apply an external magnetic field to the absorber. The energy of the radiation is therefore Doppler shifted to

$$E = E_0 \left(1 + \frac{v}{c}\right)\left(1 - \frac{v^2}{c^2}\right)^{-1/2} \tag{3.12}$$

where E_0 is the photon energy when the source is at rest. The source velocities that are required to cover the energy range of a typical Mössbauer spectrum are usually less than 1 m s^{-1}, thus $v/c \ll 1$ and a very good approximation of the above equation is

$$E = E_0 \left(1 + \frac{v}{c}\right) \quad \text{or} \quad \Delta E = E_0 \frac{v}{c} \tag{3.13}$$

Because of the energy modulation by source velocity, the energy scale in a Mössbauer spectrum is customarily presented in terms of the source velocity. For example, 1 mm s^{-1} corresponds to an energy shift of 4.80×10^{-8} eV for a ^{57}Fe Mössbauer spectrum ($E_0 =$ 14.4 keV).

The source is driven by a velocity transducer, generally operating in the velocity scan mode. The drive coil converts an applied current to the velocity of a shaft. A pickup coil provides a signal proportional to the actual velocity; a negative feedback circuit ensures accuracy and stability. The radiation source is attached to one end of the shaft, and a prism (or a mirror) for measuring velocity is mounted on the other end. The source thus scans periodically through the velocity range of interest, the simplest way of scanning velocity being constant acceleration.

The most widely employed detectors are gas proportional counters and NaI(Tl) scintillation counters, followed by semiconductor detectors. A detector should have a high efficiency and energy resolution, as well as quick response time. Typically, a gas proportional counter has a cylindrical metal tube (cathode) filled with a mixture of gases and a metal wire on the axis (anode). Operating under a high voltage of 1500–3000 V, the gas proportional counter has a high signal-to-noise ratio and a high count rate. The NaI(Tl) scintillation counters are made of sodium iodine crystals doped with thallium with detection efficiency as high as 100% and are easy to use. The semiconductor detector is essentially a p–n junction, with a reverse-biased high voltage, creating a region that is sensitive to γ-rays. They offer the best resolution over the entire range of energies of interest in Mössbauer experiments, and their efficiency is comparable to proportional or scintillation counters.

In Mössbauer spectroscopy, the absorber is usually the sample to be investigated. In the transmission geometry, the thickness of the absorber should be carefully chosen as it significantly affects the quality of the spectrum. When the sample is too thin, it would contain too few Mössbauer nuclei, resulting in weak spectral intensity, high background, and large statistical uncertainty. When the sample is too thick, significant atomic absorption would occur, causing a decrease in resonant absorption and distortion in the spectral shape. Obviously, there should be an optimal thickness between these two extremes. The effective thickness of the absorber is defined by

$$t_a = n_a f_a \sigma_0 d \tag{3.14}$$

where n_a is the number of Mössbauer nuclei in the absorber per milligram, f_a is the recoil-free fraction of the absorber, σ_0 is the maximum resonance cross section (in centimeter squared), and d is the thickness of the absorber (in milligrams per centimeter squared). For most of the absorption experiments, the effective thickness should be $t_a \approx 1$.

Sample preparation for the absorber is quite straightforward. Metallic or alloy samples are usually wrought or roll-milled into foils of the appropriate thickness. If only small pieces of sample foils are available, they may be arranged to cover the entire sample area with as few gaps and overlaps as possible. Most of the materials are in the powder form, which can be pressed to the desired thickness between two pieces of thin plastic sheets. For low-temperature measurements, the powder sample is usually mixed with a solid chemical of light atoms such as a sugar, and pressed into a "free-standing" sample. For high-temperature measurements, the powder sample is usually placed between two pieces of boron nitride sheets. Liquid samples are usually sealed in the sample holder and refrigerated until frozen. ^{57}Fe has a relatively low natural abundance; if the ^{57}Fe content in the sample is not sufficient to give a satisfactory spectrum, ^{57}Fe enrichment in the sample may be necessary.

The Mössbauer spectrometer may also include an external magnetic field (static or high frequency) to be applied to the absorber or the source. Sample temperature may be varied by using an oven or by using a cryogenic system. Windows for γ-rays to enter and exit the sample chamber should be made from a low-atomic-number element, such as beryllium.

Emission Mössbauer spectra may also be recorded from a transmission spectrometer, where the source is the material under investigation and the absorber is a well-characterized material.

In addition to the transmission geometry, Mössbauer effect can be utilized in the scattering geometry, which does not require a thin sample but probes into the surface of bulk materials. Experiments in the scattering geometry can detect not only the elastically scattered γ-rays but also the accompanying conversion electrons (conversion electron Mössbauer spectroscopy, CEMS), the X rays following the conversion events (conversion X-ray Mössbauer spectroscopy), or the inelastically scattered γ-rays (Mössbauer diffraction).

3.6
The Shape and Intensity of a Spectral Line

Because the nuclear excited state has a certain natural width Γ_s, the emitted γ-rays from a Mössbauer source are not completely monochromatic, but follow the Lorentzian distribution around E_γ (the Breit–Wigner formula),

$$\mathcal{L}(E)dE = \frac{\Gamma_s}{2\pi}\frac{1}{(E - E_\gamma)^2 + \Gamma_s^2/4}dE \tag{3.15}$$

After a resonant absorption, the nuclei in the absorber are in the excited state (with a natural width of Γ_a). They decay to the ground state through internal conversion or γ-ray emission in all directions. The cross section of resonant absorption of γ-rays (as a function of photon energy E)

is also described by the Breit–Wigner formula:

$$\sigma_a(E) = \sigma_0 \frac{\Gamma_a^2/4}{(E - E_\gamma)^2 + \Gamma_a^2/4} \tag{3.16}$$

where the maximum resonance cross section is

$$\sigma_0 = \frac{\lambda^2}{2\pi} \frac{1 + 2I_e}{1 + 2I_g} \frac{1}{1 + \alpha} \tag{3.17}$$

λ is the wavelength of the γ-ray, I_e and I_g are the nuclear spins of the excited and ground states, respectively, and α is the internal conversion coefficient.

A Mössbauer absorption spectrum is a record of transmitted γ-ray counts through the absorber as a function of γ-ray energy. Since the experiment involves both emission and absorption, we expect the line shape to be a convolution of the emission spectrum and the absorption cross section. Assuming a single-line emission and single-line absorption, we have

$$\begin{aligned}\sigma_a^{\exp}(E) &\propto \int_{-\infty}^{+\infty} \mathcal{L}(E - x)\sigma(x)dx \\ &= \frac{\sigma_0 \Gamma_a}{\Gamma_a + \Gamma_s} \frac{(\Gamma_s + \Gamma_a)^2/4}{(E - E_\gamma)^2 + (\Gamma_s + \Gamma_a)^2/4}\end{aligned} \tag{3.18}$$

which also has a Lorentzian shape, with a full width at half maximum equal to $\Gamma_s + \Gamma_a$ (the sum of the natural widths of the Mössbauer nuclei in the source and the absorber).

Experimentally, we usually measure resonance absorption by detecting the transmitted or scattered γ-rays. The vertical axis of a Mössbauer spectrum records the counts of detected γ-photons. In the transmission geometry, the original total intensity I_0 emitted from the source includes both recoil-free and recoiled γ-rays. After going through the absorber, the intensity is reduced mainly through two absorption processes: Mössbauer resonant absorption and nonresonant atomic absorption. When the source velocity does not meet the resonance condition, only the second process takes place and we observe an ideally flat baseline of the spectrum. When the source velocity is within the linewidth of absorption, resonant absorption significantly reduces the transmitted γ-rays and the spectrum shows an intensity minimum at the center of the resonance. The amount of maximum absorption may range from a few percent to 40% of the baseline count. The inverted peak can be characterized by parameters such as position of the resonance, full width at half-maximum absorption, and depth and area of the resonance line. When spectra are obtained in the scattering geometry, similar parameters are used, except that peaks representing the detected γ-rays, X rays, or conversion electrons are now above the baseline.

The horizontal axis of a Mössbauer spectrum is customarily labeled by the source velocity in millimeters per second. Velocity calibration is usually done by certain standard samples. For example, metallic α-iron is commonly used to determine the zero of source velocity and the scale of energy shift for ^{57}Fe spectra. The energy scale may also be independently calibrated by using a Michelson interferometer installed at the end of the oscillating shaft of the velocity transducer.

Since $\Gamma_s \approx \Gamma_a \sim 10^{-8}$ eV and E_γ is typically 10^4 eV, the energy resolution of a Mössbauer line can be as good as 10^{-12}. Because of this extremely high energy resolution, Mössbauer spectroscopy is ideally suited for studying hyperfine interactions.

3.7
Hyperfine Interactions

Because of the interactions between the nucleus and the surrounding electrons, nuclear energy levels are slightly altered and certain energy degeneracies are lifted. Some of the Mössbauer spectral lines will shift and others will split because of hyperfine interactions. These interactions are mainly electromagnetic but must be treated using quantum mechanics. The energies involved may be as small as 10^{-8} eV. Hyperfine interactions with nuclei at their ground states were initially observed in optical spectroscopy, followed by more accurate measurements from resonance experiments such as nuclear magnetic resonance (NMR) and electron paramagnetic resonance (EPR). Mössbauer spectroscopy offers an extra dimension of advantage. In addition to its high energy resolution, Mössbauer effect allows the observation of interactions between electrons and the nuclei in excited states, not just those in the ground state.

There are three main types of hyperfine interactions in Mössbauer effect:

1. electric monopole interaction (E0), which causes isomer shift δ, a shift of the entire resonance spectrum;
2. magnetic dipole interaction (M1), which causes magnetic hyperfine splittings of the spectral lines (Zeeman splittings);
3. electric quadrupole interaction (E2), which causes quadrupole splittings.

The electric dipole interaction (E1) is forbidden by parity requirement, and all interactions of higher orders (M2, E3, etc.) are much weaker to be detected.

3.7.1
Isomer Shift

We assume that a nucleus of atomic number Z is a uniformly charged sphere (monopole) when it is either in the ground state (with radius R_g) or in the excited state (with radius R_e). These radii have finite values and are different ($R_g \neq R_e$), although each is nearly zero compared with the size of an electron orbit. Let $\psi(0)$ represent the wave function of an s-electron within the volume of the nucleus ($r < R_g$, $r < R_e$, or practically, $r \approx 0$). The Coulomb energy between the nuclear charge and the s-electron's presence within the nuclear volume can be calculated to be

$$E_g = S(Z)Ze\frac{2\pi}{5}R_g^2 e|\psi(0)|^2 \quad \text{and}$$
$$E_e = S(Z)Ze\frac{2\pi}{5}R_e^2 e|\psi(0)|^2 \tag{3.19}$$

for the nuclear ground state and excited state, respectively. In these expressions, $S(Z)$ is the relativity factor due to relativistic effects in heavy elements (Shirley, 1964). Since the ground state is now raised by E_g and the excited state is raised by E_e, γ-transition energy is modified accordingly by

$$\Delta E = \frac{2\pi}{5}S(Z)Ze^2\left(R_e^2 - R_g^2\right)|\psi(0)|^2 \tag{3.20}$$

The same type of interaction occurs in the absorber (ΔE_a) as well as in the source (ΔE_s). Since the source and the absorber are usually not chemically identical, $\psi_a(0)$ differs from $\psi_s(0)$. As a consequence, the γ-photon energy change ΔE_a in the absorber is not identical to ΔE_s in the source. These energy changes are reflected in the Mössbauer spectrum as a shift of each line by an amount equal to

$$\delta = \frac{2\pi}{5} S(Z)\, Ze^2 \left(R_e^2 - R_g^2\right) \times \left(|\psi_a(0)|^2 - |\psi_s(0)|^2\right) \qquad (3.21)$$

This is due to two concomitant differences: one difference between the nuclear radius R_g in the ground state and its counterpart R_e in the excited state (a nuclear isomer), and the other difference between the s-electron density $\psi_a(0)$ in the absorber and its counterpart $\psi_s(0)$ in the source. This spectral shift δ is known as the *isomer shift* because of the volume difference in the nuclear isomers. It is also known as *chemical shift*, referring to its origin from the difference in chemical properties of the source and the absorber. The first difference is a fixed parameter once a nuclear isotope is chosen, whereas the second difference reflects the chemical contrast between the source and the absorber. In Mössbauer spectroscopy, we exploit the latter difference by using a series of absorbers of different chemical environments, for example, different oxidation states and coordination numbers.

Isomer shift is a relative quantity. If the nucleus increases in size when excited ($R_e > R_g$), the isomer shift increases linearly with the absorber's electron density $e|\psi_a(0)|^2$. For ^{57}Fe, the nucleus volume actually decreases when excited ($R_e < R_g$), and the isomer shift behavior is the opposite. The actual value of isomer shift depends on the choice of not only the source but also the calibration standard. Therefore, when reporting experimental results, it is important to state the type of source (e.g., ^{57}Co in rhodium matrix) and the reference point for isomer shift (e.g., with respect to the spectral center of α-Fe at room temperature). Typical ranges of isomer shifts for iron compounds in various oxidation states and spin states are available in the literature, for example, in Gibb's *Principles of Mössbauer Spectroscopy* (Gibb, 1976).

The isomer shift has been extensively investigated in many areas of chemistry and in materials science. Using isomer shift for studying the electronic structure in solids has been considered an extremely useful experimental method. The isomer shift δ can provide important information on the character of a chemical bond, as well as on oxidation state, spin state, electronegativity of a ligand, coordination number, and so on. A large amount of experimental isomer shift data has been accumulated to date; however, the interpretation of these results is not an easy task. The main difficulty is the lack of a unified model for the chemical bonds that can satisfactorily explain the isomer shift data. For practical applications, isomer shift measurements from a series of samples of similar properties are usually required. Through a comparative study, one can extract information on the electronic structure.

It should be pointed out that Mössbauer effect is so far the only method that can measure isomer shift, because the nuclear volume of the excited state is involved. The information on the electronic structure provided by isomer shift is not available from NMR, EPR, or any other methodologies.

3.7.2
Magnetic Dipole Interaction

The interaction between the nuclear magnetic dipole moment $\boldsymbol{\mu}$ and the magnetic field $\boldsymbol{B}$ produced at the site of nucleus by the surrounding electrons

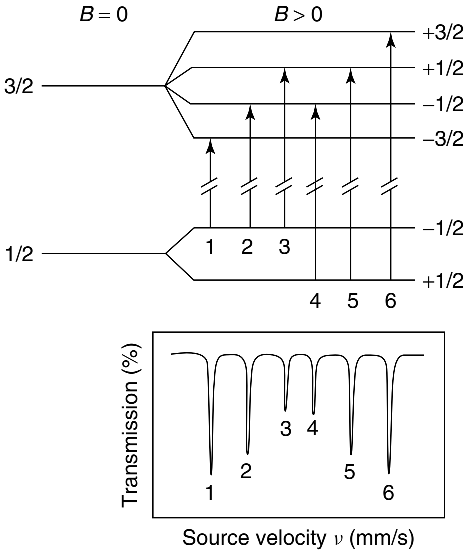

Fig. 3.5 Magnetic splittings of the ^{57}Fe nuclear energy levels and a sextet in the Mössbauer spectrum due to magnetic splittings.

or ions is called *the magnetic hyperfine interaction*. For a nucleus of spin $I \geq 1/2$, this interaction lifts the degeneracy of the energy level and splits it into $(2I + 1)$ sublevels, similar to the Zeeman effect in atomic spectroscopy. This type of splitting in the nuclear ground state had been observed in NMR and EPR. Using Mössbauer effect, nuclear Zeeman effect was first observed by Hanna *et al.* (1960).

The Hamiltonian of the interaction between a nuclear magnetic dipole moment $\boldsymbol{\mu}$ and a magnetic field $\boldsymbol{B}$ is

$$\mathcal{H}_M = -\hat{\mu} \cdot B = -g\mu_N \hat{I}_z B \tag{3.22}$$

where g is the dimensionless nuclear g-factor ($g = \mu/I\mu_N$), μ_N is the nuclear Bohr magneton (5.05×10^{-27} J T^{-1}), and the z-axis is along the direction of the magnetic field. The corresponding sublevel energies are

$$E_M = -gmB\mu_N \tag{3.23}$$

where $m = I, I - 1, \ldots, -I$.

The first excited state of ^{57}Fe has a spin of $I_e = 3/2$ and splits into four sublevels equally separated by $g_e B\mu_N$. The ground state has a spin of $I_g = 1/2$ and splits into two sublevels separated by $g_g B\mu_N$, as shown in Figure 3.5. The g_g-factor of the ground state, in general, is different from g_e of the excited state (for ^{57}Fe, $g_e = -0.1031$ and $g_g = 0.1808$). Therefore, the separation between the sublevels in the ground state is different from that in the excited state. Since the nuclear transition in ^{57}Fe is of the magnetic dipole type (M1), it can take place provided the selection rule ($\Delta m = \pm 1$ or 0) is obeyed. Thus there are only six allowed transitions, resulting in a sextet in the absorption spectrum as shown in Figure 3.5. The transitions with $\Delta m = \pm 2$ are forbidden.

The position of each line in the characteristic sextet can be easily calculated on the basis of values of $g_e B\mu_N$ and $g_g B\mu_N$. The separation between lines 3 and 4 equals $(g_g - |g_e|)B\mu_N$, while all other separations between adjacent lines are each equal to $g_g B\mu_N$.

The intensity of each absorption line is proportional to the transition probability, which can be calculated using the Clebsch–Gordan coefficients. Assuming a thin absorber with an isotropic recoil-free fraction f, we arrive at the following symmetric intensity ratio of the six absorption lines:

$$3:\frac{4\sin^2\theta}{(1+\cos^2\theta)}:1:1:\frac{4\sin^2\theta}{(1+\cos^2\theta)}:3 \tag{3.24}$$

where θ is the angle between the magnetic field $\boldsymbol{B}$ and the γ-ray direction. When the magnetic field is aligned with the γ-ray direction ($\theta = 0°$), the relative intensities of the sextet are in the ratio of 3 : 0 : 1 : 1 : 0 : 3. When the magnetic field is perpendicular to the γ-ray direction ($\theta = 90°$), the ratio is 3 : 4 : 1 : 1 : 4 : 3. If the magnetic field vectors at the nuclei are randomly oriented, then an integration over the entire solid angle gives an intensity ratio of 3 : 2 : 1 : 1 : 2 : 3.

A convenient way to describe the magnetic hyperfine interaction relies on the use of the effective magnetic field $\boldsymbol{B}_{\text{eff}}$, which has two major contributions: a local magnetic field $\boldsymbol{B}_{\text{loc}}$ at the Mössbauer nucleus by the lattice and a hyperfine magnetic field $\boldsymbol{B}_{\text{hf}}$ by the Mössbauer atom's own electrons,

$$\boldsymbol{B}_{\text{eff}} = \boldsymbol{B}_{\text{loc}} + \boldsymbol{B}_{\text{hf}} \tag{3.25}$$

The local field by the lattice may be due to the material's magnetic ordering, or may be applied externally, or both. It may have the following contributions:

$$\boldsymbol{B}_{\text{loc}} = \boldsymbol{B}_{\text{ext}} - D\boldsymbol{M} + \frac{4\pi}{3}\boldsymbol{M} \tag{3.26}$$

where $\boldsymbol{B}_{\text{ext}}$ is an external field, $\boldsymbol{M}$ is magnetization, $D\boldsymbol{M}$ represents the demagnetization field, and $4\pi\boldsymbol{M}/3$ represents the Lorentz field. In general, the local field is much smaller than the hyperfine field. The hyperfine field $\boldsymbol{B}_{\text{hf}}$ has three contributions:

$$\boldsymbol{B}_{\text{hf}} = \boldsymbol{B}_s + \boldsymbol{B}_L + \boldsymbol{B}_D \tag{3.27}$$

The first term $\boldsymbol{B}_s$ is called the *Fermi contact field* produced by spin polarization of *s*-electrons within the volume of the nucleus, and may be expressed as

$$\boldsymbol{B}_s = -\frac{4\mu_0}{3}\mu_B \sum_n [|\psi_{ns\uparrow}(0)|^2 - |\psi_{ns\downarrow}(0)|^2] \tag{3.28}$$

where μ_B is the Bohr magneton (9.27×10^{-4} J T^{-1}), $|\psi_{ns\uparrow}(0)|^2$ and $|\psi_{ns\downarrow}(0)|^2$ represent the *ns* spin-up and spin-down electron densities within the nucleus volume, respectively. The spin polarization of the *s*-electrons is caused by unpaired *d*-electrons because of an exchange interaction that slightly reduces the repulsion between electrons of the same spin. In iron compounds, $\boldsymbol{B}_s$ may range from 20 to 60 T and is the largest among the three terms in $\boldsymbol{B}_{\text{hf}}$, owing to a large number of unpaired *d*-electrons.

The second term $\boldsymbol{B}_L$ is called the *orbital field* owing to the orbital motions of the unpaired electrons around the nucleus. This motion constitutes a circular current, which in turn produces a magnetic field at the nucleus:

$$B_L = -\frac{\mu_0}{2\pi}\mu_B\langle r^{-3}\rangle\langle L\rangle \quad \text{or}$$
$$B_L = -\frac{\mu_0}{2\pi}\mu_B\langle r^{-3}\rangle(g-2)\langle S\rangle \tag{3.29}$$

where $\langle L\rangle$ and $\langle S\rangle$ are the expectation values of the orbital and spin angular momenta of the unpaired electrons.

For Fe^{3+}, $g \approx 2$, and consequently $\boldsymbol{B}_L \approx 0$. But for high-spin Fe^{2+}, $\boldsymbol{B}_L \approx 20$ T (opposite to $\boldsymbol{B}_s$) and, as expected, $\boldsymbol{B}_L$ values in rare-earth compounds are relatively large.

The third term $\boldsymbol{B}_D$ is the dipole field at the nucleus, produced by the total spin magnetic moment of the valence electrons. It can be written as

$$B_D = \frac{\mu_0}{8\pi}\mu_B \langle r^{-3}\rangle \langle 3\cos^2\theta - 1\rangle \langle S\rangle \tag{3.30}$$

$\boldsymbol{B}_D$ is obviously zero for a charge distribution with a cubic symmetry. For Fe group ions, $\boldsymbol{B}_D$ is small even in noncubic systems, ranging only from 0 to 8 T. However, in rare-earth compounds where the orbital momentum is not quenched, $\boldsymbol{B}_D$ can be quite large.

Since the separation between the lines of a sextet is proportional to the effective field $\boldsymbol{B}_{\text{eff}}$, in which the magnetic hyperfine field $\boldsymbol{B}_{\text{hf}}$ usually dominates, we can easily deduce $\boldsymbol{B}_{\text{hf}}$ from the spectrum. It is often very strong ($\boldsymbol{B}_{\text{hf}} \approx -33$ T in α-Fe) and it is local (within the vicinity of the nucleus). To measure the sign of the magnetic hyperfine field, we may apply an external magnetic field of 2 to 5 T to the sample and detect whether $\boldsymbol{B}_{\text{eff}}$ increases or decreases. When it increases, $\boldsymbol{B}_{\text{hf}}$ is positive; otherwise it is negative.

Mössbauer effect has found extensive applications in magnetism and in research of magnetic materials. Without requiring an applied external magnetic field, Mössbauer spectroscopy can be used to study the temperature dependence of spontaneous magnetization, the magnitude and orientation of hyperfine fields, and the magnetic structure of new materials. It can also be used to measure the ordering temperatures (T_C, T_N) and spin reorientation temperature, to determine phase transitions and phase compositions, to study magnetic lattice anisotropy and relaxation phenomena, and so on. Magnetism arises mainly from the atomic magnetic moments. Transition metals ($3d, 4d, 5d$), the lanthanides ($4f$), and the actinides ($5f$) all have unfilled valence electrons and have atomic magnetic moments. Fortunately, many isotopes of these elements are Mössbauer nuclei, for example, ^{57}Fe, ^{61}Ni, ^{99}Ru, ^{149}Sm, ^{151}Eu, ^{155}Gd, ^{159}Tb, ^{161}Dy, ^{165}Ho, ^{166}Er, ^{169}Tm, ^{170}Yb, ^{193}Ir, and ^{237}Np. Obviously, ^{57}Fe is most utilized because iron is the most important element in magnetism. The field of magnetism would not be as successful without Mössbauer spectroscopy.

3.7.3
Electric Quadrupole Interaction

If a nucleus (in either the ground state or an excited state) has a spin $I \geq 1$, it possesses an electric quadrupole moment eQ. For a nucleus surrounded by an asymmetric charge distribution, there is an electric field gradient (EFG), described by a tensor $\nabla \boldsymbol{E}$, at the site of the nucleus. In general, the EFG tensor contains nine second-order derivatives of electric potential ($V_{xy} = \partial^2 V/\partial x \partial y$, etc.). By choosing the principal z-axis along the highest gradient direction, we can diagonalize the EFG tensor so that $|V_{zz}| \geq |V_{xx}| \geq |V_{yy}|$. Since it is also traceless, $V_{xx} + V_{yy} + V_{zz} = 0$, only two independent parameters are needed to describe EFG. Customarily, V_{zz} is represented by eq, and the quantity $(V_{xx} - V_{yy})/V_{zz}$ is represented by η, known as the *asymmetry parameter* ($0 \leq \eta \leq 1$).

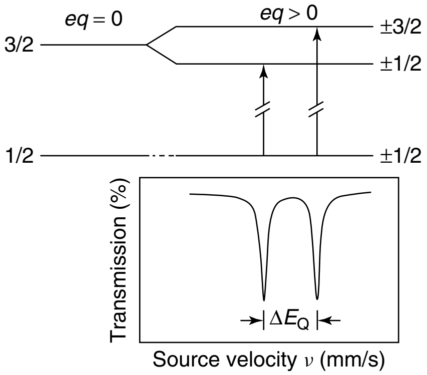

Fig. 3.6 Quadrupole splitting of the ^{57}Fe excited state and a doublet in the Mössbauer spectrum.

The Hamiltonian of this electric quadrupole interaction is

$$\mathcal{H}_Q = e\hat{Q}\nabla E = \frac{e^2qQ}{4I(2I-1)} \times \left[3\hat{I}_z^2 - \hat{I}^2 + \frac{1}{2}\eta(\hat{I}_+^2 + \hat{I}_-^2)\right] \tag{3.31}$$

where $\hat{I}_+ = \hat{I}_x + i\hat{I}_y$ and $\hat{I}_- = \hat{I}_x - i\hat{I}_y$ are the raising and lowering operators, respectively. The eigenvalues of this Hamiltonian are

$$E_Q(m) = \frac{e^2qQ}{4I(2I-1)}[3m^2 - I(I+1)] \times \left(1 + \frac{\eta^2}{3}\right)^{1/2} \tag{3.32}$$

where $m = I, I-1, \ldots -I$.

The ^{57}Fe excited state (14.4 keV) has a nuclear spin of $I = 3/2$, and this energy level splits into two sublevels ($m = \pm 3/2$ and $m = \pm 1/2$) due to quadrupole interaction. Because only m^2 appears in Eq. (3.32), each sublevel is still doubly degenerate. The energy eigenvalues of the two sublevels are

$$E_0 + E_Q\left(\pm\frac{3}{2}\right) = E_0 + \frac{e^2qQ}{4}\left(1 + \frac{\eta^2}{3}\right)^{1/2} \tag{3.33}$$

$$E_0 + E_Q\left(\pm\frac{1}{2}\right) = E_0 - \frac{e^2qQ}{4}\left(1 + \frac{\eta^2}{3}\right)^{1/2} \tag{3.34}$$

The ground state of ^{57}Fe has $I = 1/2$, so $Q = 0$, and the energy level does not split, as shown in Figure 3.6. Therefore, in the absence of Zeeman splitting, nuclear transition may take place from the ground state to either of the two excited states, resulting in a doublet in the Mössbauer spectrum, as shown in Figure 3.6. The separation between the two resonance lines, known as *quadrupole splitting*, is

$$\Delta E_Q = \frac{e^2qQ}{2}\left(1 + \frac{\eta^2}{3}\right)^{1/2} \tag{3.35}$$

Assuming an isotropic recoil-free fraction f, the relative intensities of the spectral lines of the quadrupole doublet in a single crystal can be calculated as

$$I_{\pm 3/2} = \frac{C}{\sqrt{1 + (\eta^2/3)}}\left(4\sqrt{1 + (\eta^2/3)} + 3\cos^2\theta - 1 + \eta\sin^2\theta\cos 2\phi\right) \tag{3.36}$$

$$I_{\pm 1/2} = \frac{C}{\sqrt{1+(\eta^2/3)}}\left(4\sqrt{1+(\eta^2/3)} - 3\cos^2\theta + 1 - \eta\sin^2\theta\cos 2\phi\right) \tag{3.37}$$

where C is a constant, and θ and ϕ are the polar and azimuthal angles of the incident γ-ray direction in the EFG principal-axis system. In the case of an axially symmetric EFG ($\eta = 0$), the intensity ratio of the two absorption lines is

$$\frac{I_{\pm 3/2}}{I_{\pm 1/2}} = \frac{1+\cos^2\theta}{\frac{5}{3}-\cos^2\theta} \tag{3.38}$$

For a polycrytalline sample or a powder sample, the crystal axes are randomly oriented. Integrating over the entire solid angle for each intensity, we obtain

$$\frac{\langle I_{\pm 3/2}\rangle}{\langle I_{\pm 1/2}\rangle} = \frac{\frac{1}{4\pi}\int I_{\pm 3/2}\sin\theta\, d\theta\, d\phi}{\frac{1}{4\pi}\int I_{\pm 1/2}\sin\theta\, d\theta\, d\phi} = 1 \tag{3.39}$$

If the recoil-free fraction is not isotropic but $f(\theta)$ is angular dependent, the above integrals must each be weighted by $f(\theta)$ and the ratio will not be 1 (a manifestation of the Goldanskii–Karyagin effect),

$$\frac{\langle I_{\pm 3/2}\rangle}{\langle I_{\pm 1/2}\rangle} = \frac{\frac{1}{4\pi}\int I_{\pm 3/2}f(\theta)\sin\theta\, d\theta\, d\phi}{\frac{1}{4\pi}\int I_{\pm 1/2}f(\theta)\sin\theta\, d\theta\, d\phi} \neq 1 \tag{3.40}$$

The quadrupole splitting $\Delta E_Q = 1/2e^2q\, Q(1+\eta^2/3)^{1/2}$ as measured from a Mössbauer spectrum only provides the product of eQ and eq, not their individual values or their signs. The nuclear quadrupole moment eQ is a fixed parameter for a particular isotope and may be independently measured (especially that of the ground state). The size and sign of the z-component of EFG eq ($= V_{zz}$) is determined by partially filled valence orbitals (valence) as well as by the charges on the neighboring ions and ligands surrounding the Mössbauer atom (lattice). Theoretical calculations of total V_{zz} at the site of the nucleus gave the following result:

$$V_{zz} = (1-R)(V_{zz})_{\text{val}} + (1-\gamma)(V_{zz})_{\text{lat}} \tag{3.41}$$

where $(V_{zz})_{\text{val}}$ and $(V_{zz})_{\text{lat}}$ are contributions from valence and lattice, respectively, each with an empirical parameter R (Sternheimer shielding factor) and a γ (Sternheimer antishielding factor) (Sternheimer, 1966). Therefore, ΔE_Q provides information on the symmetry of local chemical and electronic environment (oxidation state and spin state). Both $(V_{zz})_{\text{val}}$ and $(V_{zz})_{\text{lat}}$ are inversely proportional to r^3. Since the valence electrons are closer to the nucleus than the lattice charges, the former is much larger than the latter. For high-spin $^{57}\text{Fe}^{3+}$, the valence shell is $3d^5$ (exactly half filled), and $(V_{zz})_{\text{val}} = 0$ because of symmetry. For high-spin $^{57}\text{Fe}^{2+}$, the sixth electron in $3d^6$ is the main source of EFG. The quadrupole splitting for Fe^{2+} ($\Delta E_Q \approx 3.0\ \text{mm s}^{-1}$) has been found to be much larger than that for Fe^{3+} ($\Delta E_Q \approx 0.5\ \text{mm s}^{-1}$). The ΔE_Q values in low-spin $^{57}\text{Fe}^{2+}$ ($<0.8\ \text{mm s}^{-1}$) are smaller than the ΔE_Q values in low-spin $^{57}\text{Fe}^{3+}$ (0.7–$1.7\ \text{mm s}^{-1}$), again reflecting the one-electron difference in their d-orbitals.

$(V_{zz})_{\text{val}}$ may be strongly temperature dependent when a crystal field with lower-than-cubic symmetry splits the orbital energy levels. These suborbitals will be populated according to Boltzmann distribution, and hence the temperature dependence, which is reflected in the Mössbauer spectra taken at different temperatures (Chen *et al.*, 1992).

3.7.4
Combined Electric Quadrupole and Magnetic Dipole Interactions

When the above three hyperfine interactions are simultaneously present, the combined Hamiltonian is

$$\mathcal{H} = \mathcal{H}_{\mathrm{IS}} + \mathcal{H}_M + \mathcal{H}_Q \tag{3.42}$$

where the isomer shift Hamiltonian $\mathcal{H}_{\mathrm{IS}}$ is independent of the nuclear spin I, but both the magnetic dipole $\mathcal{H}_M$ and electric quadrupole $\mathcal{H}_Q$ Hamiltonians involve the same operator $\hat{I}$. When $\mathcal{H}_M$ and $\mathcal{H}_Q$ are considered separately, the quantization axis (the z-axis) for $\hat{I}$ in $\mathcal{H}_M$ is most conveniently chosen as the direction of the magnetic field $\boldsymbol{B}$; for $\hat{I}$ in $\mathcal{H}_Q$ it is along one principal axis of the EFG tensor. When both $\boldsymbol{B}$ and EFG are present, it is likely that the magnetic field is not aligned with the EFG principal axis. The combined Hamiltonian therefore takes a more complicated form:

$$\begin{aligned}\mathcal{H} = \mathcal{H}_{\mathrm{IS}} &+ \frac{e^2qQ}{4I(2I-1)} \\ &\times \left[3\hat{I}_z^2 - \hat{I}^2 + \frac{1}{2}\eta(\hat{I}_+^2 + \hat{I}_-^2)\right] \\ &- g\mu_N B\left\{\left[\frac{1}{2}(\hat{I}_+ + \hat{I}_-)\cos\phi \right.\right. \\ &\left. + \frac{1}{2}(\hat{I}_+ - \hat{I}_-)\sin\phi\right] \\ &\left. \times \sin\theta + \hat{I}_z \cos\theta \right\}\end{aligned} \tag{3.43}$$

where the z-axis is along the EFG principal axis, and θ and ϕ are the Euler angles describing the magnetic field direction within the EFG principal axes system. It is possible to obtain analytical solutions of eigenvalues and eigenvectors of this Hamiltonian, which involves the mixing of all original states and consequently allows the previously "forbidden" transitions (Häggström, 1974). To obtain complete analytical solutions is a tedious procedure and the solutions are very complicated for practical purposes.

In several special cases, the analysis is greatly simplified. When the EFG is axially symmetric ($\eta = 0$) and its z-axis happens to be aligned with the magnetic field $\boldsymbol{B}$ ($\theta = 0$), $\mathcal{H}_M$ and $\mathcal{H}_Q$ commute. The Zeeman states of $\mathcal{H}_M$ are also eigenvectors of $\mathcal{H}_Q$, and the new energy levels are simply combinations of the original E_M and E_Q:

$$\begin{aligned}E(m) &= E_{\mathrm{IS}} + E_M + E_Q \\ &= E_{\mathrm{IS}} - gmB\mu_N \\ &\quad + (-1)^{|m|+1/2}\frac{e^2qQ}{4}\end{aligned} \tag{3.44}$$

The Zeeman energy levels are no longer equally spaced; in the case of $I = 3/2$, the inner two energy levels are shifted in one direction and the outer two in the opposite direction.

It is often the case where either the magnetic hyperfine interaction or electric quadrupole interaction is dominant while the other occurs as a perturbation. For example, electric quadrupole interaction in a magnetically ordered solid is much weaker than the magnetic hyperfine interaction. On the other hand, an externally applied magnetic field to a paramagnetic material may result in a magnetic hyperfine interaction much weaker than the existing electric quadrupole interaction.

When the magnetic hyperfine interaction dominates, the energy levels are

$$E(m) = E_{\mathrm{IS}} - gmB\mu_N + (-1)^{|m|+1/2}\frac{e^2qQ}{4} \times \frac{3\cos^2\theta - 1 + \eta\sin^2\theta\cos 2\phi}{2} \tag{3.45}$$

which is similar to the previous case, except that the additional shift now depends on the relative angles (θ and ϕ) between the EFG and the magnetic field $\boldsymbol{B}$, as well as on the EFG's asymmetry parameter (η). When the electric quadrupole interaction dominates, the two states corresponding to $m = \pm 1/2$ will mix and give the following two different energy levels:

$$E(\pm ½) = E_{\mathrm{IS}} \pm \frac{1}{2}gB\mu_N \times \sqrt{4 - 3\cos^2\theta} - \frac{e^2qQ}{4} \tag{3.46}$$

and the two states corresponding to $m = \pm 3/2$ have the following energy levels:

$$E(\pm \tfrac{3}{2}) = E_{\mathrm{IS}} \pm \frac{3}{2}gB\mu_N\cos\theta + \frac{e^2qQ}{4} \tag{3.47}$$

Compared with the perfectly aligned and symmetric EFG cases, spectra from these more general cases are more difficult to analyze, but they allow us to extract more information, such as the sign of the EFG component V_{zz} and the relative direction of the hyperfine magnetic field.

3.7.5
Saturation Effect in the Presence of Hyperfine Splittings

It has been observed that in a sextet spectrum due to a magnetic hyperfine field the spectral intensities (absorption areas A) do not strictly follow the theoretical predictions of 3 : 2 : 1 : 1 : 2 : 3 for powder samples. This is because the area A is not a linear function of the effective thickness t_a of the absorber, but has a smaller slope for a larger t_a, manifesting a saturation effect as shown in Figure 3.7. Among the six absorption lines, each pair comes from participation of only one portion of the total population of Mössbauer nuclei: lines 1 and 6 are due to one-half of the total population, lines 2 and 5 are due to one-third of them, and lines 3 and 4 are due to only a sixth. Therefore, each pair corresponds to a different partial effective thickness. Because of the nonlinear saturation

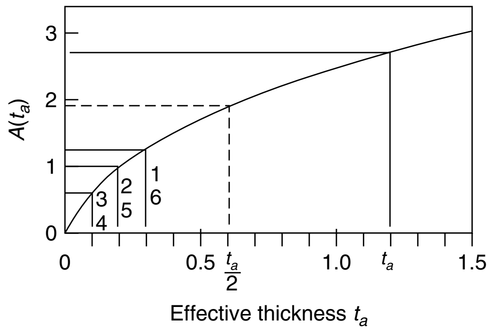

Fig. 3.7 Absorption area A as a function of effective thickness t_a. Because of the saturation effect, $2A\left(\frac{t_a}{2}\right) > A(t_a)$, and $12A\left(\frac{t_a}{12}\right) > 6A\left(\frac{t_a}{6}\right) > 4A\left(\frac{t_a}{4}\right)$.

effect, the absorption areas are not strictly in the ratio of 3 : 2 : 1, but $x : y : 1$, with $x < 3$ and $y < 2$.

Another important aspect is that the splitting of a single line will result in an increase of the total absorption area. Suppose a single line (effective thickness t_a) has an area of $A(t_a)$. When it splits into two sublines (each of partial effective thickness $\frac{t_a}{2}$), the total area is $2A(\frac{t_a}{2})$, which is clearly larger than $A(t_a)$, as illustrated in Figure 3.7.

When the absorption intensities are measured and used to infer any quantitative conclusions about the structural or chemical composition of the absorber, the saturation effect must be carefully taken into account.

3.8
Second-Order Doppler Effect

The second-order Doppler effect is a relativistic effect that results in the shift of the entire spectrum. Expanding Eq. (3.12) and retaining up to the second-order term, we obtain

$$\Delta E = E_0 \left(\frac{v}{c} - \frac{v^2}{2c^2} \right) \tag{3.48}$$

When atomic vibrations in the absorber are considered, their average velocity strongly depends on temperature. The corresponding Doppler shift is then

$$\langle \Delta E \rangle = -E_0 \frac{\langle v^2 \rangle}{2c^2} \tag{3.49}$$

This second-order Doppler effect modifies the energy of the γ-rays. In a Mössbauer spectrum, second-order Doppler shift δ_{SOD} is manifested as a relative quantity between the source and the absorber:

$$\delta_{\mathrm{SOD}} = \frac{\langle \Delta E \rangle}{E_0} = \frac{\langle v^2 \rangle_s - \langle v^2 \rangle_a}{2c^2} \tag{3.50}$$

where $\langle v^2 \rangle_s$ and $\langle v^2 \rangle_a$ are the mean-square velocities of the source and absorber, respectively.

Both the isomer shift and second-order Doppler shift have the effect of displacing the entire Mössbauer spectrum. They can be separated by utilizing the fact that the second-order Doppler shift depends strongly on temperature while the isomer shift is a measure of the s-electron density at the nucleus and approximately temperature-independent. Because the specific behavior of $\langle v^2 \rangle$ is determined by lattice vibration, δ_{SOD} is also useful in studying lattice dynamics.

3.9
Applications of Mössbauer spectroscopy

Mössbauer spectroscopy is mainly used to study the properties of materials through hyperfine interactions. Isomer shift, quadrupole splitting, magnetic hyperfine field, second-order Doppler effect, and the recoil-free fraction are all important parameters in Mössbauer spectroscopy. They are determined by the positions and the areas of spectral lines, as well as the spectral shapes and linewidths. These parameters also depend on external conditions such as temperature, pressure, and magnetic field. It is clear that Mössbauer spectra can provide an abundance of information.

Using hyperfine interactions, Mössbauer effect serves as a bridge linking the nucleus with its environmental details, including the crystal structures of materials, the perfectness of a crystal, lattice periodicity, magnetic ordering, the amorphous state, oxidation state in a compound, coordination number, effect of ligands, and the vibrations and diffusions of atoms in the solid. Because of its extremely diverse applications, Mössbauer spectroscopy has developed into a truly unique interdisciplinary field of science.

The isomer shift (chemical shift) δ provides information about the chemical environment, because of its sensitivity to changes in electron density at the site of the nucleus. Any changes in oxidation state, spin state, valence orbitals, type of chemical bond, ligand electronegativity, coordination number, substitutional or interstitial impurities, and so on, will be reflected in the isomer shift. Because it is often difficult to separate these causes, an investigation of a series of similar samples is usually required, and a comparison of their isomer shift data then provides unequivocal conclusions. In ^{57}Fe Mössbauer spectroscopy, isomer shift is very sensitive to the oxidation and spin states of iron. The δ-value (relative to α-Fe) is typically in the range from $+0.8$ to $+1.5$ mm s^{-1} for high-spin Fe^{2+} ($S = 2$), but in a distinctively different range of -0.2 to $+0.5$ mm s^{-1} for low-spin Fe^{+2} ($S = 0$). For Fe^{3+}, the isomer shift values for low spin ($S = 1/2$) and high spin ($S = 5/2$) are, respectively, $-0.2 - +0.4$ mm s^{-1} and $+0.2 - +0.6$ mm $^{-1}$s (Gibb, 1976). They overlap in the region from $+0.2 - +0.4$ mm s^{-1}; if a compound's isomer shift falls in this region, an independent determination of the spin state is required. Also, the two low-spin ions Fe^{2+} and Fe^{3+} have almost identical isomer shift values, but fortunately their quadrupole splittings are quite different, allowing unambiguous determinations of these two oxidation states.

The quadrupole splitting provides information about the lack of symmetry of the local electronic environment in which the nucleus resides. The asymmetry arises from nonspherical molecular orbitals or noncubic ligand coordination from the surrounding lattice. When combined with isomer shift data, quadrupole splitting values reflect the space group of local symmetry, the types of orbitals, relative orientations of local chemical bonds, and so on. Quadrupole splitting values may also be used to distinguish long-range and short-range orders in solids of less perfect lattices, such as amorphous materials and metallic glasses. Quadrupole splittings are also observed in magnetic materials, especially when they are in the paramagnetic phase, in the form of spin glasses, or in the superparamagnetic configuration. The behavior of quadrupole splitting as a function of temperature can be used to determine the respective phase transition temperatures.

The ubiquitous sextet ^{57}Fe Mössbauer spectrum, because of magnetic hyperfine interaction, contains a wealth of information about the magnetic properties of the material. Combined with result from bulk magnetic measurements, a spectrum with a sextet or several superimposed sextets indicates whether the material is ferromagnetic, antiferromagnetic, or ferrimagnetic. Fitting the experimental spectrum according to energy values of the Hamiltonian, we obtain parameters such as hyperfine magnetic field and isomer shift, which in turn allows us to calculate the magnetic moment of the atom. Experiments over a wide range of temperatures are beneficial for detecting magnetic phase transitions and for establishing a relationship between hyperfine magnetic field $\boldsymbol{B}_{\mathrm{hf}}$ (at the nuclear site) and the exchange field $\boldsymbol{B}_E$ (causing spontaneous magnetic ordering). For most magnetic ordered materials, $\boldsymbol{B}_{\mathrm{hf}}$ and $\boldsymbol{B}_E$ are proportional to each other, and they have identical temperature dependence. Therefore, information from Mössbauer spectroscopy can be directly correlated to macroscopic magnetic measurements (e.g., magnetization) as well as other microscopic measurements (e.g., NMR and muon resonance). For amorphous magnetic materials, the Mössbauer sextet is usually poorly resolved and broadened; it may be necessary to use a continuous distribution of hyperfine magnetic fields, instead of a few discrete values, to fit the spectrum.

Mössbauer spectroscopy has a particular timescale, characterized by the lifetime of the excited state from which the γ-rays are emitted. Usually of the order of 0.1 microseconds, this timescale τ is fast for many atomic processes, but it is slow relative to certain fluctuating mechanisms. Therefore, it is convenient to use Mössbauer spectroscopy to study materials that involve weak interactions between atoms, molecules, or clusters where relaxation times τ_0 may be comparable to τ. An example is superparamagnetism in which nanosized magnetic particles undergo fast thermal fluctuations, the magnetic hyperfine interaction is averaged out, and only quadrupole interaction is observed (Yang *et al.*, 2003). At lower temperatures when fluctuation slows down, hyperfine magnetic field begins to be observed. Near the so-called blocking temperature, a Mössbauer spectrum may reveal both coexisting phases, each with broadened spectral lines.

An external magnetic field may be applied to the absorber. A constant DC magnetic field applied to a magnetic material will allow us to determine the direction of the hyperfine field with respect to the atomic magnetic moment and, in the case of ferrimagnetic material, the direction and size of each component. When a constant external magnetic field is applied to a nonmagnetic material, one may observe Zeeman splittings as a perturbation to the quadrupole interaction, which will elucidate the direction of EFG relative to the crystallographic axes when the sample is a single crystal. An external high-frequency magnetic field may be applied to a soft magnetic material to induce a fast fluctuation of the hyperfine magnetic field, and therefore eliminate the Zeeman splittings in the Mössbauer spectrum, revealing only the quadrupole splittings and simplifying the analysis (Kopcewicz, 1989).

Other applications of Mössbauer spectroscopy include the following: measuring nuclear properties, testing general theory of relativity (Pound and Rebka, 1959; Kholmetskii, 2000), elucidating mechanism of catalysis (Jiang *et al.*, 2002), identifying minerals and ores (Stevens, 1998), studying corrosion in civil engineering (Cook, 2004), classifying chemical compositions of extraterrestrial samples and meteorites (Morris *et al.*, 2004), determining protein functions in biology (Bauminger and Harrison, 2003), analyzing iron compounds in atmospheric aerosols (Kopcewicz and Kopcewicz, 2000), exploring possibility of cancer therapy (Mills *et al.*, 1988), characterizing painting pigments in fine arts (Kuno *et al.*, 2004; Keisch, 1973), and archaeometry (Lazzarini *et al.*, 1980).

Mössbauer spectroscopy has enjoyed continued success because of the following extraordinary characteristics and advantages:

1. It has decisively the highest energy resolution of all spectroscopic methods.
2. Traditional Mössbauer spectroscopy requires only a relatively simple apparatus, in contrast to other nuclear physics research systems that are usually huge in size and exorbitantly expensive.
3. It is a nondestructive method for studying a solid and obtains microscopic statistical information on the atomic scale rather than a macroscopic average.

Mössbauer spectroscopy complements other nuclear methods such as neutron scattering, perturbed angular correlation, and nuclear magnetic resonance.

Like other experimental methods, Mössbauer spectroscopy has its own limitations. Although the total number of Mössbauer isotopes now exceeds 100, some of them have very short half-lives, and others require liquid-nitrogen or even liquid-helium temperatures for the observation of Mössbauer effect. By and large, for most isotopes, either the corresponding sources are very expensive or their Mössbauer effect is difficult to observe. ^{57}Fe remains to be the best Mössbauer isotope. Iron is found in a large array of materials. Many minerals have certain amount of Fe, magnetic materials are largely based on Fe, and there are numerous iron alloys and iron compounds. Because of this economic implication of iron and iron products, research using ^{57}Fe Mössbauer spectroscopy has always assumed the leading role.

Mössbauer spectroscopy has a history of 50 years since the first experiments of resonant absorption of nuclear γ-rays. New aspects of Mössbauer effect are still being investigated; especially, as SR became available, new theories and new techniques are being developed to make use of this artificial form of radiation to the fullest.

3.10
Mössbauer Spectroscopy Using Synchrotron Radiation

Electromagnetic radiation from a synchrotron accelerator may be used to observe Mössbauer effect. SR provides polarized pulsed radiation of high intensity, high collimation, and narrow beams. The only drawback is that SR is far from monochromatic. However, its energy can be adjusted and it can cover an energy range for a majority of Mössbauer transitions. The high intensity of SR sources has been utilized for scattering experiments where conventional radiation sources cannot provide adequate results. More importantly, the pulsed nature of SR radiation is most suitable for measuring time spectra – using a short SR pulse ($<10^{-10}$ seconds) to excite a nuclear ensemble, forming an "exciton" and allowing the observation of its coherent decay at different time intervals. The method of measuring time spectra is called *time-domain Mössbauer spectroscopy*, whereas the transmission method is referred to as *energy-domain Mössbauer spectroscopy*. In the last two decades, significant progress has been made in synchrotron Mössbauer spectroscopy, especially in the time-domain method, providing a direct and efficient approach to the study of Mössbauer effect and hyperfine fields. There emerged several new research areas that are not accessible with the conventional radiation sources. One example is the direct measurement of phonon DOS using SR sources. It was known that the phonon DOS could be measured, in principle, by Mössbauer effect, but because of various difficulties it was not achieved until SR became available in the 1990s. In 1999 and 2000, the journal *Hyperfine Interactions* devoted volumes 123, 124, and 125 to a comprehensive collection of 40 review articles written by the pioneers in the theory and experiments of nuclear resonant scattering of SR (Gerdau and de Waard, 1999, 2000).

The most distinct advantage of SR is its high brilliance. The brilliance of a third-generation SR source is about 9–10 orders of magnitude higher than that from a rotating target X-ray generator, and about 12 orders of magnitude higher than a ^{57}Co source of 3.7×10^8 Bq (10 mCi). SR can be tuned to the Mössbauer transition energies not only for the most common isotope ^{57}Fe but also for others such as ^{83}Kr, ^{119}Sn, ^{151}Eu, and ^{161}Dy. However, SR sources require a large and costly facility, and will not be available in ordinary Mössbauer laboratories. Therefore, the SR sources are unlikely to replace the conventional radiation sources.

3.10.1
Monochromatization of Synchrotron Radiation

The bandwidth of an SR beam is at least 10 orders of magnitude wider than the nuclear resonant width ($\sim 10^{-8}$ eV). After going through a double-crystal premonochromator Si(111), SR bandwidth can be reduced to the order of electronvolts. Further collimation and monochromatization are necessary. There are mainly two types of monochromators, one based on the scattering by electrons and the other on resonant scattering by nuclei. The first type can offer a bandwidth within a few milli electronvolts, and the second type can provide the desired bandwidth of a few micro electronvolts for nuclear resonant experiments.

Using monochromators based on electron scattering and specifically designed detectors, many lattice dynamics experiments as well as nuclear forward scattering experiments have been performed with acceptable signal-to-noise ratios, although a milli electronvolt bandwidth is still about 10^6 times wider than the resonance linewidth of ^{57}Fe. A typical scatterer contains a large number of electrons in addition to the resonant nuclei, and those electrons will nonresonantly scatter all the SR in the meV band. Therefore, only 10^{-6} of the detected photon count is due to nuclear resonant scattering. The electron scattering process is prompt in time, whereas the nuclear resonant scattering is a time-delayed process since the typical lifetime of the nuclear isomeric state is long ($\tau \sim 100$ nanoseconds) compared to the incident SR pulse ($\sim$0.1 nanoseconds). Using this time difference, photons from nonresonant electron scattering can be discriminated by a detector with nanosecond rise and fall times. For certain crystalline scatterers, we may choose specific scattering angles so that the electronic Bragg reflections are canceled or forbidden, for example, using the $(2n+1\ 2n+1\ 2n+1)$ plane in α-Fe_2O_3.

Through the use of nuclear Bragg scattering, monochromators such as single crystal ^{57}FeBO$_3$, multilayers 25× [^{57}Fe

(22 Å)/Sc(11 Å)/^{56}Fe(22 Å)/Sc(11 Å)], or the grazing incident antireflection (GIAR) film can further reduce the bandwidth to 10^{-6}–10^{-8} eV, approaching the natural width of the nuclear energy level. Because hyperfine interactions are involved in the above nuclear Bragg scattering, the resultant radiation may contain a few separate spectral lines. This multicomponent radiation may be directly used in experiment; but if a truly single-line monochromatic source is desired, an additional absorber may be added to filter out the unwanted spectral components.

The following description represents a specific example of monochromatization and polarization of SR (Smirnov, 2000). SR is first reflected off a double-crystal Si(1 1 1) monochromator, reducing the bandwidth to 2.8 eV at the nuclear resonance energy. A channel-cut Si(8 4 0) polarizer reduces the π-polarized component from 1% to less than 10^{-4} % and the bandwidth to milli electronvolts. It is then reflected off the (3 3 3) plane of a single-crystal ^{57}FeBO$_3$, placed in an oven (above its Neèl temperature to eliminate magnetic hyperfine interaction) with an external magnetic field in the (3 3 3) plane. The outcome is an extremely narrow, linearly polarized, completely recoil-free, and highly intense Mössbauer source for ^{57}Fe, equivalent to a ^{57}Co source of an enormous activity of $\sim 3.7 \times 10^{13}$ Bq (1000 Ci).

3.10.2
Time-Domain Mössbauer Spectroscopy

In time-domain Mössbauer spectroscopy (TDMS), coherent decays in resonant absorption, nuclear Bragg scattering, or forward scattering are observed at different times (~10–100 nanoseconds) after the nuclear system has been excited. Mössbauer parameters and hyperfine interactions can be studied by TDMS through the analysis of several new phenomena such as dynamical beats (DBs), quantum beats (QBs), and speed-up effect of initial decay.

In time-domain experiments, a strong pulse of SR simultaneously excites all Mössbauer nuclei in a sample and they decay in a coherent fashion. Each nucleus is no longer isolated, but interacts with others. It is possible for a nuclear excitation to propagate elastically throughout the entire ensemble of nuclei (a γ-photon emitted by one excited nucleus may be reabsorbed or scattered by other nuclei that are identical to the emitting nucleus). Without this interaction, individually excited nucleus would decay exponentially with its natural lifetime. However, an interacting ensemble of nuclei behaves differently. Such a collective nuclear excitation by an SR pulse is known as a *nuclear exciton*. Elastic decay of this exciton deviates from exponential behavior and contains intensity modulations characterized by beats.

In experiments using traditional Mössbauer radiation source, we may detect how the intensity of radiation, emitted from a source, evolves with time as it goes through an absorber. Typically, a delay coincidence circuit is used; a block diagram is shown in Figure 3.8 where an oscillating absorber allows absorption at a certain resonance velocities. In the case of traditional ^{57}Fe spectroscopy using a ^{57}Co source, it is convenient that 91% of the decay process follows a cascade through two excited states (136.5 keV → 14.4 keV → ground state). The time zero is set by the detection of a 122.1-keV photon (γ_1), which signifies that the nucleus

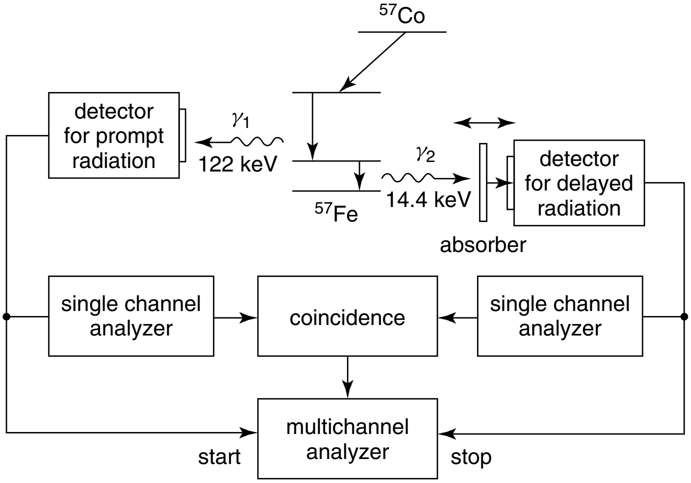

Fig. 3.8 Block diagram of the prompt and delay coincidence detection circuits.

is now in the 14.4-keV state (natural lifetime $\tau = 98$ nanoseconds). This signal starts the time measurement t until a 14.4-keV photon (γ_2) is detected. A time-domain spectrum is then constructed by plotting the number of events $N(t)$ against the time delay t. With no absorber, this curve is perfectly exponential $N(t) \propto e^{-t/\tau}$ and measures the lifetime τ. With the oscillating absorber in place, the detected γ_2 photons include those that have energies just above resonance and those just below resonance. Because these two groups of photons have very distinct dispersion characteristics (traveling through the absorber with very different speeds), $N(t)$ at the detector is an "interference pattern" instead of a purely exponential decay. It is characterized by aperiodic modulations, known as *dynamical beats* (DBs), and by the speed-up of initial decay.

Theoretically, this can be modeled as the propagation of a truncated harmonic wave through a dispersive medium, and the result is

$$N(t) \propto e^{-t/\tau} \left[J_0(\sqrt{t_a t/\tau}) \right]^2 \tag{3.51}$$

where the exponential behavior is now modulated by a Bessel function of the zeroth order J_0, oscillating aperiodically with the apparent periods increasing with time (Figure 3.9). In addition, the modulation depends on t_a, the effective thickness of the absorber. For a very thin absorber ($t_a \ll 1$) or very short times ($t \ll \tau$), we may expand the Bessel function and retain the first term. This portion of the time-domain spectrum becomes

$$N(t) \propto e^{-t/\tau} e^{-t_a t/2\tau} \tag{3.52}$$

where the second factor is also exponential, making the apparent decay rate to be $\tau/(1 + t_a/2)$, shorter than the natural lifetime τ. This phenomenon is known as *speed up* of initial decay.

DBs and speed up of initial decay can also be observed in experiments using SR, where a short pulse (~0.1

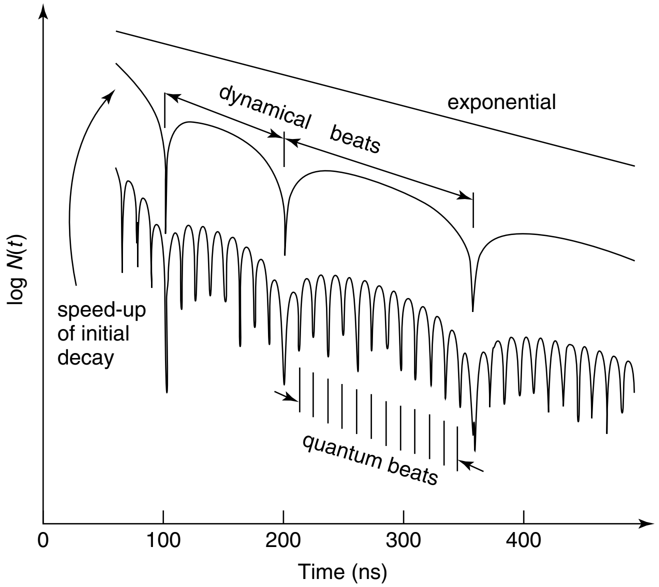

Fig. 3.9 Main features in time-domain Mössbauer spectra, showing speed up of initial decay, dynamical beats, and quantum beats.

nanosecond) of radiation of energies within a particular bandwidth is applied. The intensity of nuclear Bragg scattering or forward scattering is then observed as a function of time. (For readers familiar with pulsed NMR, this is similar to one single RF pulse followed by the observation of "free induction decay," or FID.) The theoretical treatment now requires the inclusion of all the energies within the bandwidth of the SR radiation. The resultant time-domain spectrum (DB) can be expressed in terms of a Bessel function of the first order J_1,

$$N(t) \propto e^{-t/\tau}\left[t_a \frac{J_1(\sqrt{t_a t/\tau})}{\sqrt{t_a t/\tau}}\right]^2 \qquad (3.53)$$

For $t_a \ll 1$ and $t \ll \tau$, we have again the speed up of initial decay:

$$N(t) \propto t_a^2 e^{-t/\tau} e^{-t_a t/4\tau} \qquad (3.54)$$

with an apparent rate of $\tau/(1 + t_a/4)$.

When the scatterer contains hyperfine interactions and therefore allows multiple resonant scatterings, another interference phenomenon takes place: periodic modulations (known as *quantum beats* (*QBs*)) are now superimposed onto the DBs, as shown in Figure 3.9. For example, a scatterer with two resonance energies E_1 and E_2 would give

$$N(t) \propto e^{-t/\tau}\left[t_a \frac{J_1(\sqrt{t_a t/\tau})}{\sqrt{t_a t/\tau}}\right]^2 \times \cos^2\left(\frac{E_2 - E_1}{2\hbar}t\right) \qquad (3.55)$$

In this case, the QBs are periodic and they contain information about the hyperfine splitting.

Comparing time-domain Mössbauer spectroscopy with energy-domain Mössbauer spectroscopy, we find similarities and differences. Both are phenomena of nuclear resonance. The energy-domain

Mössbauer spectra are mainly based on resonance absorption. The transmitted counts of photons are measured as functions of their energies (an energy spectrum), which represents an incoherent sum of the spectral components of the transmitted radiation. In other words, the transmitted spectrum reflects the incoherent process of nuclear resonance absorption by individual nuclei. By contrast, time-domain Mössbauer spectroscopy belongs to the scattering method. A scattering spectrum measured as a function of time is a coherent sum of the spectral components of the scattered radiation from nuclei collectively excited by an SR pulse. This leads to those important interference effects in TDMS.

A time-domain spectrum may be Fourier-transformed to an energy-domain spectrum. A purely exponential time-domain spectrum gives a familiar Lorentzian energy spectrum. However, time-domain spectra with QB and DB will give energy-domain spectra with interesting shapes, such as a double-hump structure.

3.10.3
Applications of Time-Domain Mössbauer Spectroscopy

Time-domain Mössbauer spectroscopy has found many applications, among which measurements of the recoil-free fraction f and the phonon DOS are perhaps the most interesting and the easiest to understand. (Strictly speaking, one does not measure the recoil-free fraction f directly in scattering experiments, but use the Lamb–Mössbauer factor f_{LM}. In an isotropic scatterer, f_{LM} and f are identical.)

In the time domain, we measure the recoil-free fraction f through determining t_a because they are linearly related according to Eq. (3.14), $t_a = n_a f \sigma_0 d$. Using nuclear forward scattering, t_a may be extracted from the speed up of initial decay or from the minimum positions of DBs. An excellent set of experiments has been carried out using, as the scatterer, a polycrystalline α-Fe foil of thickness of 11 μm and a 95% ^{57}Fe enrichment (Bergmann *et al.*, 1994). A magnetic field of 0.6 T was applied in the plane of the foil so that only the $\Delta m = 0$ transitions were allowed. As the scatterer temperature was varied between 9.7 and 1048 K, time-domain Mössbauer spectra were obtained using SR of bandwidth 10 meV. A large time window was open to observe as many periods of DB as possible so that t_a could be deduced more accurately. The time spectra contained both QBs and DBs, from which temperature dependence of the magnetic hyperfine field $\boldsymbol{B}_{\mathrm{hf}}$ were determined from the QB periods and that of the Lamb–Mössbauer factor f_{LM} from the DB "periods." The results were in excellent agreement with traditional energy-domain Mössbauer spectroscopy and bulk magnetic measurements.

Using SR of energy resolution 6 meV tuned precisely at the Mössbauer transition energy, inelastic nuclear resonant scattering has been applied to measure the phonon DOS directly (Sturhahn *et al.*, 1995). A very short pulse (<0.1 nanosecond) of SR excites essentially all electrons and nuclei in the scatterer. Nonresonantly scattered radiation (by nuclei other than the Mössbauer isotope and all electrons) appears promptly in time (within a few nanoseconds), whereas photons that are resonantly absorbed by a Mössbauer nuclei need a delayed time (comparable to the natural life time of the excited state) to be reemitted. The prompt nonresonantly scattered radiation was eliminated by only counting in a time window of 30 to 600 nanoseconds after the arrival of the SR flash. Photons with precisely the Mössbauer transition energy will naturally cause nuclear resonance and hence elastic scattering. Photons with less energy can also excite nuclear resonance by annihilation of a phonon (lattice vibration), and photons with more energy can excite nuclear resonance by creation of a phonon. The probability of annihilation or creation of phonons is proportional to the local DOS. By detecting the delayed *K*-fluorescence radiation due to conversion electrons caused by the deexcitation of the Mössbauer nuclei, the phonon DOS can be directly measured. This phonon spectrum can also be normalized and integrated to give the recoil-free fraction f or the Lamb–Mössbauer factor f_{LM}, which provides an alternative method independent of isotope abundance, sample thickness, resonance cross section, or hyperfine interactions.

3.11
Synchrotron Methods versus Conventional Methods

Synchrotron Mössbauer spectroscopy has attracted a significant amount of attention from researchers and become a well-established methodology in the last decade. SR provides extremely strong and narrow photon beams, which facilitates spectral measurement under special experimental conditions, such as high temperature, high pressure, high magnetic field, and working with small samples ($\sim$1 mm^2) or nanostructured thin films. In biological samples, the concentration of Mössbauer isotope is usually too low for conventional Mössbauer spectroscopy, but SR should be strong enough to produce detectable signals. Usually, results for the recoil-free fraction f from synchrotron Mössbauer spectroscopic have higher accuracy than results from the conventional methods, partly due to the absence of the saturation effect in synchrotron Mössbauer methods. Scattering experiments require only relatively short measurement time, ranging from a few minutes to a few hours. The conventional Mössbauer spectroscopy may require up to hundreds of hours. Hyperfine parameters measured from synchrotron experiments have accuracies comparable with those from conventional experiments. In QB experiments, sufficient data accumulation is required in the chosen time window to yield satisfactory measurements of the periods.

Perhaps the most important contribution from synchrotron Mössbauer spectroscopy is its ability to measure phonon DOS directly. So far, this has not been achieved by conventional Mössbauer spectroscopy. Phonon DOS may be deduced from inelastic neutron scattering by extracting force constants from the fitted dispersion curves. However, on using inelastic nuclear resonant scattering with SR where the Mössbauer nuclei serve as analyzers, phonon DOS can be measured without phonon dispersion relations; hence this is a model-independent and more accurate method. Furthermore, inelastic nuclear resonant scattering allows us to measure *partial* density of states (PDOS) related to a specific isotope or a particular impurity.

However, synchrotron Mössbauer spectroscopy suffers from several shortcomings. Because time-domain experiments are based on the interference phenomenon, the corresponding spectra are very complex, whereas conventional Mössbauer spectra provide certain direct visual information. If two or more hyperfine fields are involved, time spectra may be severely modulated. The second major drawback of synchrotron Mössbauer spectroscopy is obviously the high expenses in constructing and maintaining such a large centralized synchrotron facility. Synchrotron Mössbauer spectroscopy is an important supplement to the conventional Mössbauer spectroscopy. The former will never completely replace the latter, but will help solve problems that cannot be studied or solved satisfactorily by using conventional methods.

11.1
Introduction

An overview of spectroscopy fundamentals for atoms and molecules is provided as they pertain to the ultraviolet (UV) and visible spectral regions. Topics include state labels, electronic selection rules, the Born–Oppenheimer approximation, and the Franck–Condon principle. The Beer–Lambert law, chemometrics, derivative spectroscopy, and circular dichroism (CD) spectroscopy are explained as are the origins of UV/visible transitions in organic and inorganic compounds as well as solids. Relevant experimental methods and instrumentation such as light sources, monochromators, and detectors, which can be used to record UV/visible absorption spectra, are described. A brief discussion on laser-based techniques, including fluorescence excitation spectroscopy, excitation spectroscopy with mass detection, and cavity ring-down spectroscopy, is also given.

11.2
Spectral Background

Absorption occurs when electromagnetic radiation interacts with matter resulting in a loss of beam intensity after passing through the sample. Light absorption can take place in the gas phase, liquid phase, solid phase, or in a plasma, and can involve a single species or a complex mixture.

The UV spectral region lies between ~200 and 400 nm while the longer wavelength visible region lies between ~400 and 700 nm. The conversions to frequency (ν), cm^{-1} wave number ($\tilde{\nu}$), and energy (E) units are presented in Table 11.1.

UV/visible photons are usually sufficiently energetic to promote electrons from the atomic or molecular ground states to higher lying valence or Rydberg states. In the case of molecules, the energy can also excite excited-state vibrational and rotational motions.

11.2.1
State Labels

11.2.1.1 Atoms

The orbital angular momentum of an electron in an atom can only adopt integer values : $\ell = 0, 1, 2,$ and so on. The total orbital angular momentum of a many-electron system **L** can be calculated from the vector sum $\mathbf{L} = \overrightarrow{\sum_i \ell_i}$. Although **L** can only have integer

Tab. 11.1 Wavelength, λ, frequency, ν, wave number, $\tilde{\nu}$, and energy, E, ranges for the ultraviolet and visible spectral regions.

Range	λ (nm)	ν (Hz)	$\tilde{\nu}$ (cm^{-1})	E (J)
UV	200–400	1.5×10^{15}–7.5×10^{14}	50 000–25,000	9.94×10^{-19}–4.97×10^{-19}
Visible	400–780	7.5×10^{14}–3.8×10^{14}	25 000–12820.5	4.97×10^{-19}–$2.52 \times 10^{1-19}$

values = 0, 1, 2, and so on, it should be appreciated that a single multielectron configuration can often lead to many values of **L**. The terms are called $S, P, D, F \ldots$ when $L = 0, 1, 2, 3 \ldots$, respectively (Bernath, 1995).

Each electron has spin $s = 1/2$ and the total electron spin of the system can be calculated from the vector sum $\mathbf{S} = \sum_i \mathbf{s}_i$, where $\mathbf{s}_i$ is the electron spin of electron, i. A singlet state arises when the total electron spin is zero. This terminology comes from the definition of the spin multiplicity = $2S + 1$. If the total spin of a state is $S = 1(2S + 1 = 3)$, then the term is called a *triplet state*. One-electron systems or atoms with unpaired electrons can have terms with half-integer total electron spin; that is, $S = 1/2$, $3/2$, $5/2$, and so on, leading to doublet states, quartet state, sextet states, and so on. These arguments hold for molecules as well.

The total angular momentum, **J**, can be calculated in two ways. For light atoms with relatively few electrons (typically, atoms with atomic numbers $Z < 40$), **J** can be deduced from the vector sum of **L** and **S** (Russell–Saunders coupling scheme). Again one term with specific values of **L** and **S** can give rise to many J-levels. Russell–Saunders atomic terms are labeled by ${}^{2S+1}L_J$.

For heavier atoms, the individual electron orbital and spin angular momenta, $\vec{\ell}_i$ and $\mathbf{s}_i$ first vector-couple to form total angular momenta $\mathbf{j}_i$. The total angular momentum for the system is found from the vector sum $\mathbf{J} = \sum_i \mathbf{j}_i$ (j–j coupling scheme). The total angular momentum **J** can have integer or half-integer values depending on whether **S** is integer or half integer, and their numerical value serves as the label for the term.

The parity, I, of a one-electron state can be determined from $I = (-1)^{\ell}$ where ℓ is the orbital angular momentum of the electron involved. For a many-electron system, the parity is determined not by the total angular momentum L, but by a sum of the individual electron orbital angular momenta in the configuration; that is, by $I = (-1)^{\sum_i \ell_i}$. A state or term is considered even or odd depending on whether I is +1 or −1, respectively. The term symbols for an electron state would then be denoted by g (gerade; even) or u (ungerade, odd).

11.2.1.2 **Molecules**

The electronic states of diatomic or linear molecules are usually labeled by the component of orbital angular momentum along the bond axis Λ. When $\Lambda = 0, 1, 2, 3, \ldots$, the states are called Σ, Π, Δ, Φ, $\cdots$, respectively. Because linear systems have cylindrical symmetry, each state with $\Lambda > 0$ is twofold degenerate, corresponding physically to clockwise and counterclockwise electron orbital motion about the molecular axis. This degeneracy can be broken,

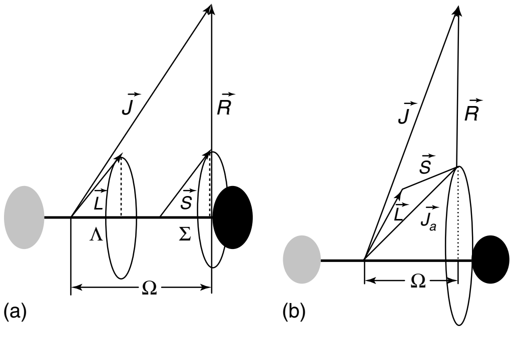

Fig. 11.1 (a) Hund's coupling case (*a*); (b) Hund's coupling case (*c*) for a diatomic molecule. **R**, **L**, **S**, and **J** refer to the rotational, orbital, spin, and total angular momenta, respectively. $\mathbf{J}_a$ is the vector sum of **L** and **S** in Hund's case (*c*). The precession of **J** about the internuclear axis in part a) is not indicated. In part (b) the precession of **L** and **S** about $\mathbf{J}_a$ or **J** about the internuclear axis is not shown. Λ, Σ, and Ω are the projections of **L**, **S** and **J** along the bond axis.

however, by molecular rotation in a process called Λ-*doubling* (Herzberg, 1950). The symmetry of Σ-states with respect to reflection in a plane containing the molecular axis σ_v must be considered. Σ-states that are symmetric with respect to σ_v are labeled Σ^+, while those that are antisymmetric with respect this symmetry operation are called Σ^-. These superscripts are not included for states with $\Lambda > 0$ since they already include +and − components. Molecular terms are denoted by ${}^{2S+1}\Lambda_\Omega$ where $\Omega = |\Lambda + \Sigma|$ is the component of total angular momentum along the molecular axis. Here Σ does not mean $\Lambda = 0$, but is instead the component of electron spin S along the bond axis, which ranges from $+S$ to $-S$ in integer steps.

The labels discussed above are appropriate for Hund's coupling case (*a*) (Figure 11.1a). There are five common coupling cases (*a*)–(*e*) (Herzberg, 1950). Hund's case (*a*) resembles the Russell–Saunders scheme presented above for light atoms. Hund's case (*c*) (Figure 11.1b) is the molecular analog of j–j coupling when spin–orbit coupling is important. Here Λ and Σ are no longer well defined, and the states are labeled only by $\Omega = 0, 1/2, 1, 3/2$, and so on, depending on the total electron spin. Again, the + and − labels must be added to the 0 states, and g and u subscripts included if needed.

The electronic states of nonlinear molecules are labeled by the Mulliken label for their irreducible representation, Γ, within their particular point group (Cotton, 1990), and again the g and u superscripts are used if appropriate.

11.2.2
Electronic Selection Rules

UV/visible transitions are induced when an incident electromagnetic field interacts with the different electric or magnetic multipole moments, $\tilde{\mathrm{M}}$, of the electron distribution of the molecule. Quantum-mechanical selection rules dictate transitions which will be observed. If ψ_e' and ψ_e'' are the upper and lower electronic states, respectively, a particular transition between these states will be allowed if the transition matrix element $\int \psi_e'^{*} \hat{\mathrm{M}} \psi_e'' d\tau_e$ is nonzero (Herzberg, 1966). Here $\hat{\mathrm{M}}$ is the operator corresponding to the particular charge distribution in the molecule, and the integration is over the electronic coordinates, τ_e. The intensity of the transition is proportional to the square of the transition matrix element although this can be very difficult to calculate. As a rule of thumb, the strongest transitions (sometimes referred to as *E1 transitions*) involve the electric dipole moment: $\hat{\mathrm{M}} = -\sum_i e_i \boldsymbol{r}_i$. E2 and $E3$ transitions involve the electric quadrupole and electric octupole moments, respectively, but are considerably weaker than E1 transitions. M1, M2, and M3 transitions involve the magnetic dipole, magnetic quadrupole, and the magnetic octupole moments, respectively, and are also relatively weak. Typically, M1 and E2 transitions are comparable in intensity. Both require high sensitivity to be detected, and usually will only be observed in frequency regions where E1 transitions are forbidden. The rest of this chapter will focus on single-photon electric dipole transitions.

There are additional symmetries that govern selection rules. Single-photon electric dipole transitions are allowed when there is a change in parity. The selection rule governing parity, the so-called Laporte selection rule, can be written for one-electron systems as $\Delta\ell = \pm 1$. For many-electron systems, the selection rule becomes $\Delta L = 0, \pm 1$.

Electron spin does not usually change during an electronic transition that leads to a $\Delta S = 0$ selection rule. The spin selection rule can be relaxed, however, when the spin–orbit interaction becomes important. Then the selection rules for **L** and **S** becomes less rigorous, and those for the total angular momentum, **J** must be considered. It can be shown that the selection rules are $\Delta J = 0, \pm 1$; $J' = 0 \leftrightarrow J'' = 0$ forbidden. The selection rule forbidding single-photon transitions between states with $J = 0$ can be understood as a consequence of conserving angular momentum in an absorption process involving photons that have their own intrinsic nonzero angular momentum.

The selection rules for linear molecules in Hund's case (*a*) are $\Delta\Lambda = 0, \pm 1$, $\Delta S = 0$, $\mathrm{g} \leftrightarrow \mathrm{u}$, $\left\{\begin{matrix}+\\-\end{matrix}\right\} \leftrightarrow \left\{\begin{matrix}+\\-\end{matrix}\right\}$. In Hund's case (*c*) the rules are $\Delta\Omega = 0, \pm 1$, $\mathrm{g} \leftrightarrow \mathrm{u}$, $\left\{\begin{matrix}+\\-\end{matrix}\right\} \leftrightarrow \left\{\begin{matrix}+\\-\end{matrix}\right\}$.

In general, a molecular transition will be allowed if the direct product of the irreducible representations of the ground-state wave function, excited-state wave function, and the multipole moment contains the totally symmetric representation of the particular point group, $\Gamma(\mathrm{A}_1)$, that is, $\Gamma(\psi_e') \otimes \Gamma(\hat{\mathrm{M}}) \otimes \Gamma(\psi_e'') \subset \Gamma(\mathrm{A}_1)$. Equivalently, a transition will be allowed if the direct product $\Gamma(\psi_e') \otimes \Gamma(\psi_e'') \subset \Gamma(\hat{\mathrm{M}})$.

11.2.3
Born–Oppenheimer Approximation and the Franck–Condon Principle

Vibrations play a significant role in determining the intensity of transitions between molecular electronic states (Hollas, 1996). An appropriate starting point is the Born–Oppenheimer approximation, which allows the electronic and nuclear motions to be considered separately because of the large mass differences between the nuclei of a molecule and an electron. Within this approximation, the total wave function of a state, Ψ, can be expressed as $\Psi(r, R) = \psi(r, R)\chi(R)$ where χ is a nuclear wave function that depends on nuclear coordinates $\{R\}$ and ψ is an electronic wave function that depends on the electronic coordinates $\{r\}$ and parametrically on the position of the nuclei. The electronic wave function is therefore found by solving the Schrodinger wave equation at fixed nuclear positions.

A potential energy surface can then be constructed by finding the electronic energy at different nuclear coordinates.

The Franck–Condon principle states that electronic transitions will occur on a much faster timescale than that it takes the nuclei to adjust to their new equilibrium positions. A single-photon electric dipole transition matrix element is defined as $\int \Psi' \hat{\mu} \Psi'' drdR$, where Ψ' and Ψ'' are the wave functions of the excited and ground state, respectively, and $\hat{\mu}$ is the electric dipole operator. As a consequence of the Born–Oppenheimer approximation, the matrix element can be written as a product of an electronic component $R_e = \int \psi' \hat{\mu} \psi'' dr$ and a vibrational overlap integral $S_{v',v''} = \int \chi'_{v'} \chi_{v''} dR$. The intensity of an electronic transition will only be appreciable if the electronic transition probability $|R_e|^2$ is nonzero. This requires that the transition obey the appropriate selection rules for the orbital and spin quantum numbers. The square of $S_{v',v''}$, called the *Franck–Condon factor,* however, modulates the intensity distribution of the vibronic bands observed for a specific electronic transition.

For the sake of simplicity, the Franck–Condon principle is illustrated here for diatomic molecules because they have only one vibrational motion (bond stretching), and therefore their potential energy surfaces reduce to potential energy curves. Quantum mechanically, except for the lowest vibrational level ($v = 0$), which has its maximum wave function amplitude at the equilibrium bond length of the molecule in that electronic state, the largest amplitudes of the vibrational wave functions for $v > 0$ are found at the classical turning points. These correspond to bond lengths where the total energy is potential energy only; that is, the turning points are bond lengths where the nuclear velocities are zero and classically the bond is either at its maximum extension (outer turning point) or its maximum compression (inner turning point). As shown in Figure 11.2(a) the ($v' = 0$, $v'' = 0$) vibronic transition will have the largest Franck–Condon factor (vibrational wave function overlap) when the ground-state equilibrium bond length r''_e, is $\approx$ the excited equilibrium bond length r'_e. The Franck–Condon principle predicts that this transition will be the most intense feature in the absorption spectrum. However when $r'_e > r''_e$ (Figure 11.2b) or $r'_e < r''_e$ the intensity maximum will no longer be the (0,0) transition. In both cases, the spectrum will exhibit a (v',0) progression with a Gaussian intensity distribution maximizing at a value of v', which depends on Δr_e.

In some molecular systems, the Franck–Condon factors are largest for vibronic transition where $v' \gg 0$. One interesting example is the transitions between the ground and ion-pair states of the diatomic halogens. There are 20 ion-pair states of a diatomic halogen XY (X and Y = Cl, Br, I) that dissociates to X^+ (^3P, ^1D, ^1S) + Y^- (^1S). The strongest transitions from their ground states terminate at the first tier $D0_u{}^+$ or $E0^+$ state depending on whether the halogen is homonuclear or heteronuclear, respectively. A molecular orbital analysis shows that these excited ion-pair states have antibonding character. However since the long-range binding is coulombic in nature, the resultant excited states have deeper potential energy curves than the ground states, longer bond lengths, and smaller vibrational frequencies. As a result, the most intense Franck–Condon transitions from

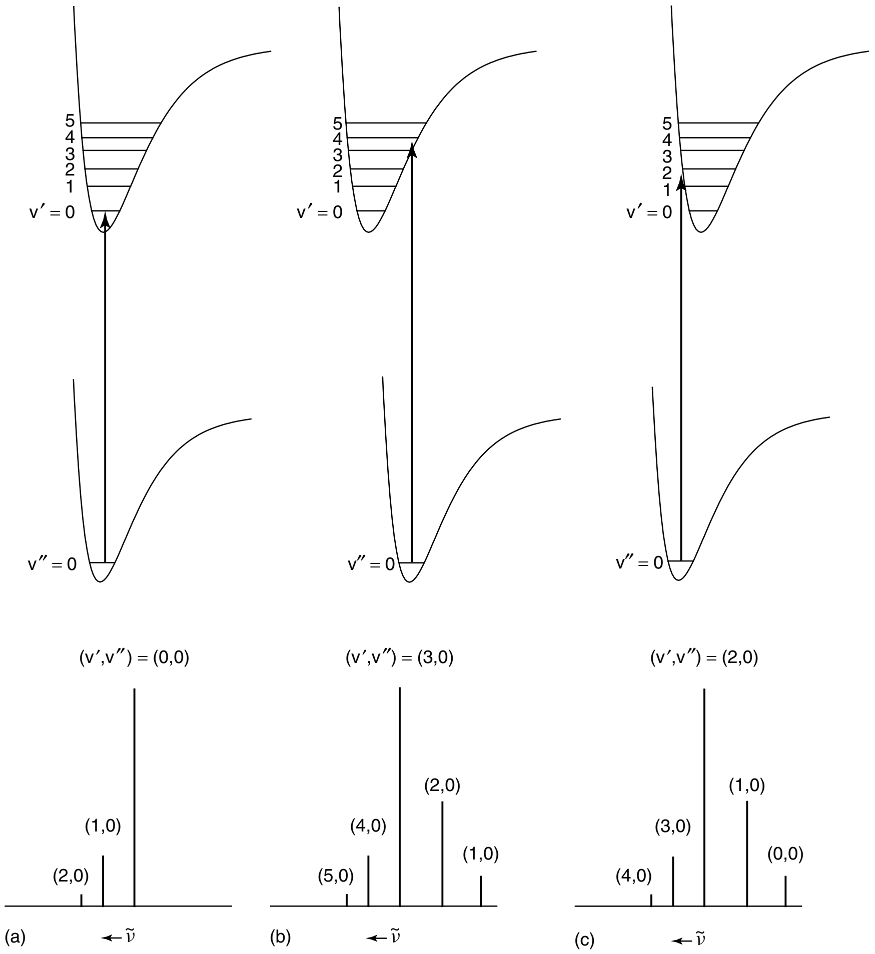

Fig. 11.2 Potential energy curves and resultant stick spectra for the case where (a) $r_e' \approx r_e''$; (b) $r_e' > r_e''$, and (c) $r_e' < r_e''$.

$v'' = 0$ of the IBr ground state, for example, probe the inner wing of the excited E0$^+$ state potential energy curve in the vacuum UV spectral region exciting high vibrational levels between $v' = 260$ and 383 (Lipson and Hoy, 1989).

In general, a vibronic transition will be allowed if $\int \psi_e'^{*} \chi_{v'} \hat{M} \psi_e'' \chi_{v''} d\tau_r d\tau_R$ is nonzero, where $\hat{M}$ is the electric dipole operator. This condition holds if $\Gamma(\psi_e') \otimes \Gamma(\chi_{v'}) \otimes \Gamma(\hat{M}) \otimes \Gamma(\psi_e'') \otimes \Gamma(\chi_{v''}) \subset \Gamma(A_1)$. Within the Born–Oppenheimer approximation, the vibronic transition matrix element will be a product of $3N - 6$ (nonlinear molecules) or $3N - 5$ (linear molecules) vibrational overlap integrals. At room temperature, the ground-state population resides primarily in $v'' = 0$ of the normal modes. These states transform as the total symmetric representation of the molecular point group. If the excited-state vibration is totally symmetric the selection rule on v is $\Delta v_i = 0, \pm 1, \pm 2, \ldots$. If the vibration is nontotally symmetric the Franck–Condon factor vanishes when $\Delta v_i = \pm 1, \pm 3, \pm 5, \ldots$ because $\Gamma(\chi_{v'}) \otimes \Gamma(\chi_{v''})$ does not contain the totally symmetric representation. The selection rule therefore becomes $\Delta v_i = \pm 2, \pm 4, \pm 6, \ldots$.

A series of vibronic transitions originating from a common lower vibrational state and probing a range of excited vibrational states is called a *progression*. For example, the progression originating from the lowest ground-state vibrational level would be ($v' = 0, 1, 2, \ldots, v'' = 0$), and the intensities of the observed bands are determined by their Franck–Condon factors. Vibronic transitions where $\Delta v = v' - v'' =$ constant (a positive or negative integer) form *sequences*. For example, a $\Delta v = 0$ sequence would be made up of the (0,0), (1,1), (2,2), ... transitions. Since the population in $v'' > 0$ is expected to be small for most normal modes, hot-band progressions (originating from $v'' > 0$) and sequence transitions involving $v'' > 0$ are not expected to be particularly intense.

11.2.4
Rotational Fine Structure

Usually, rotational fine structure can only be resolved for molecules in the gas phase, where, typically, the linewidths found in UV/visible spectra are Doppler-broadened. Rotationally resolved spectra are much more difficult to obtain for liquid- or solid-phase samples where other line broadening mechanisms are operative.

A full discussion regarding the rotational fine structure associated with electronic transitions of molecules is beyond the scope of this chapter. Instead, a short discussion pertaining to diatomic molecules is presented here. The rotational selection rules for diatomic molecules (Hund's case (*a*), when $\Delta\Lambda = 0, \pm 1$) are $\Delta J = J' - J'' = 0, \pm 1$ where J' and J'' are the upper and lower state rotational quantum numbers. This leads to three branches labeled P ($\Delta J = -1$), Q ($\Delta J = -1$), and R ($\Delta J = +1$). However, only P and R branches are found for electronic transitions where $\Delta\Lambda = 0$, $\Lambda' = \Lambda'' = 0$. This can be understood by conservation of angular momentum arguments. On the other hand, if $\Delta\Lambda = 0$, $\Lambda' = \Lambda'' \neq 0$, the three branches are allowed but the Q-branch will be weak, while the P and R branches will be strong.

The wave number ($\tilde{\nu}$) expressions for these branches ignoring centrifugal distortion effects, are given by

$$\begin{aligned}
\tilde{\nu}_P &= \tilde{\nu}_o - (B_{v'} + B_{v''})J'' \\
&\quad + (B_{v'} - B_{v''})J''^2 \\
\tilde{\nu}_Q &= \tilde{\nu}_o + (B_{v'} - B_{v''})J''(J'' + 1) \\
\tilde{\nu}_R &= \tilde{\nu}_o + 2B_{v'+} + (3B_{v'} - B_{v''})J'' \\
&\quad + (B_{v'} - B_{v''})J''^2
\end{aligned} \tag{11.1}$$

where $B_{v'}$ and $B_{v''}$ are the upper and lower state rotational constants in states v' and v'', respectively, and $\tilde{\nu}_o$ is the "pure" vibronic band origin. A B_v-value is inversely proportional to bond length, r_v, in a particular vibronic state, and hence a detailed rotational analysis can provide quantitative details about the upper and lower state vibronic geometries. These values can be used to find the equilibrium structure of the molecule.

The equations in Eq. (11.1) are quadratic in J. If $B_{v'} > B_{v''}$, that is, $r_{v'} < r_{v''}$, the rotational line spacings will decrease in the P-branch and increase in the R-branch. At some value of

J'' a band head will form, which is characteristic edge structure (in low resolution) composed of many rotational lines. The observed vibronic bands will be degraded to the higher energies (blue-shaded). Conversely, if $B_{v'} < B_{v''}$, that is, $r_{v'} > r_{v''}$, the spacings will decrease in the R-branch and increase in the P-branch. The resultant vibronic bands will then be red-shade.

11.3
Absorption Spectra

11.3.1
Beer–Lambert Law

In general, a UV/visible absorption spectrum is found by recording a plot of transmitted light versus wavelength. Experimentally, the amount of absorption or absorbance, A, is determined by measuring the transmitted light intensity, I, relative to the incident light intensity I_o using

$$A = -\log_{10}\left(\frac{I}{I_o}\right) \tag{11.2}$$

The absorbance, which is unitless and is sometimes called the *optical density*, is proportional to the number of molecules in the path of the beam, and can therefore in the solution phase be calculated using the Beer–Lambert law:

$$A = \varepsilon(\lambda)[C]\ell \tag{11.3}$$

where $\varepsilon(\lambda)$, which is the absorption coefficient of the sample at a specific wavelength, λ, $[C]$ is the sample concentration, and ℓ is the path length. ε is also called the *molar absorptivity* or *molar extinction coefficient* and has units of L mol^{-1} cm^{-1} when $[C]$ and ℓ are expressed in molarity and centimeters, respectively. An analogous expression can be written for gas-phase samples using number densities (in molecules per centimeter cubed) instead of concentrations. Then, the absorption coefficient is identified as an absorption cross section, σ (centimeter squared). The molar extinction coefficient is related to σ by

$$\varepsilon = \sigma(N_0 - N_1) \tag{11.4}$$

where N_0 and N_1 are the ground-state and excited-state number densities, respectively.

Typically, ε (in liters per mole per centimeter) can vary between 0 and 10^6 where values $\geq 10^4$ are related to high-intensity absorptions while values $<10^3$ are considered low-intensity absorptions. Forbidden transitions will have molar absorptivities ranging from 0 to $\sim 10^3$.

If more than one species exists in solution, the overall absorbance will be equal to the sum of the absorbances of the individual species. For an N-component mixture, A can be written as

$$A(\lambda) = \ell \sum_{i=1}^{N} \varepsilon(\lambda)[C_i] \tag{11.5}$$

The spectrum of a solution containing a pair of absorbing species can exhibit one or more isosbestic points, which correspond to wavelengths where the molar absorptivities of the species are identical. Even when a 1 : 1 reaction occurs the absorbance of a solution of the two reactants and product at an isosbestic point will remain invariant to the degree of reaction; that is, independent of their particular concentrations.

The Beer–Lambert law assumes that A will be a constant if the product of $[C]$ and ℓ is constant. However, this may not always be the case. For example, there could be molecular association at higher concentrations, or the species could undergo photochemistry upon irradiation. The Beer–Lambert law may also fail for acids, bases, and salts that exhibit concentration-dependent ionization, for samples that are strongly fluorescent, or if a thermal equilibrium exists between the ground state and a low-lying excited state. As a result, the linearity associated with the Beer–Lambert law should always be confirmed experimentally before an analysis.

11.3.2
Chemometrics

As noted above the Beer–Lambert law is additive. This allows the composition of a mixture of compounds to be determined if their individual absorption spectra are known. This technique lends itself very well to analysis by computer software. The field where mathematical or statistical methods are applied to data analysis is called *chemometrics*. The basic approach can be illustrated by considering a mixture of three compounds, a, b, and c with concentrations $[C_a]$, $[C_b]$, $[C_c]$ respectively (Rouessac and Rouessac, 2007). The absorbance of this mixture is measured at three wavelengths λ_1, λ_2, and λ_3 resulting in three measurements A_1, A_2, and A_3, respectively. By using a path length of $\ell = 1$ cm the absorbances at the three wavelengths can be written in matrix form as

$$\tilde{\mathrm{A}} = \tilde{\varepsilon}\tilde{\mathrm{C}} \tag{11.6}$$

where

$$\tilde{\mathrm{A}} = \begin{pmatrix} A_1 \\ A_2 \\ A_3 \end{pmatrix}, \quad \tilde{\varepsilon} = \begin{pmatrix} \varepsilon_a^1 & \varepsilon_b^1 & \varepsilon_c^1 \\ \varepsilon_a^2 & \varepsilon_b^2 & \varepsilon_b^2 \\ \varepsilon_a^3 & \varepsilon_b^3 & \varepsilon_c^3 \end{pmatrix}$$

$$\text{and} \quad \tilde{\mathrm{C}} = \begin{pmatrix} [C_a] \\ [C_b] \\ [C_c] \end{pmatrix}$$

If the nine absorbances in the $\tilde{\varepsilon}$ matrix are known, $\tilde{\mathrm{C}}$ can then be found by computing $\tilde{\mathrm{A}}\varepsilon^{-1}$. The precision of the composition determination can be improved for mixtures that have similar spectra by using many tens of data points, even though, mathematically, the system of equations in Eq. (11.6) would be overdetermined.

11.3.3
Derivative Spectroscopy

It can be helpful, instead of plotting A versus λ, to mathematically plot the absorbance derivatives $dA/d\lambda$ as a function of wavelength. This can be done for higher order derivatives as well. Such plots serve to amplify weak slope variations of the zeroth-order absorption spectrum. First-derivative plots will pass through zero at the location of each peak maximum, while second-derivative plots produce zero values at wavelengths corresponding to both the minima and maxima of the original absorption spectrum. This technique is useful when the zeroth-order spectrum has a uniformly increasing baseline due to a strong absorption at shorter wavelengths or because of light scattering. It is also helpful when there are weak absorbances that are overshadowed by stronger bands in the original spectrum.

11.3.4
Circular Dichroism Spectroscopy

CD spectroscopy measures the differential absorption of left-hand and right-hand circularly polarized light as a

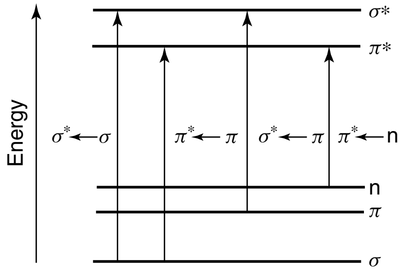

Fig. 11.3 An energy level diagram for a generic organic molecule indicating the possible types of electronic transitions, and their relative energy ordering.

function of exciting wavelength (Berova, Di bari and Pescitelli, 2007). The technique is sensitive to absolute configurations and therefore is able to discriminate different enantiomers (stereoisomers whose mirror images are not superimposable). Formally, a chiral molecule is one that does not possess an improper axis of rotation. CD is defined as

$$CD = A^L - A^R \tag{11.7}$$

where A^L and A^R are the absorptions of left and right-hand circularly polarized light, respectively. The difference in the molar absorption coefficients, $\Delta\varepsilon$, at a specific wavelength can be expressed in terms of CD by

$$\Delta\varepsilon = \varepsilon^L - \varepsilon^R = \frac{CD}{[C]\ell} \tag{11.8}$$

CD values for enantiomers are always equal and opposite, and therefore, when scanning through an absorption band $\Delta\varepsilon$ will change rapidly in one direction, pass through zero at the peak maximum, and then change rapidly in the opposite direction. This is known as the *Cotton effect* after its discoverer. Positive and negative Cotton effects refer to the cases where $\Delta\varepsilon$ is >0 and <0, respectively.

Although electric dipole moments, $\boldsymbol{\mu}_{ij}$, are larger than magnetic dipole moments, $\mathbf{m}_{ij}$, the rotational strength of a CD signal, R_{ij}, which is proportional to $\int \Delta\varepsilon d\nu$, depends on the product $\boldsymbol{\mu}_{ij} \cdot \mathbf{m}_{ij}$. R_{ij} is a signed quantity, and as such can be used to interpret CD spectra and to make configurational assignments. The assignments depend strongly on the chromophores (Section 11.4.1) and their arrangements in the molecule. In general, related complexes that have the same CD sign for a given absorption have the same absolute configuration.

11.4
The Origin of UV/Visible Transitions in Organic Molecules

A generic energy level diagram of an organic molecule is presented in Figure 11.3.

The filled molecular orbitals of an organic molecule are designated as σ-bonding, π-bonding, or nonbonding, n, depending on the nature of the atomic orbitals involved. The most probable electronic transitions will take place from the highest occupied molecular orbital (HOMO) to the lowest occupied molecular orbital (LUMO), which are typically antibonding in nature (σ^* or π^*). In general, the energies E of the possible transitions are ordered: $E(\pi^* \leftarrow n) < E(\pi^* \leftarrow \pi) < E(\sigma^* \leftarrow n) < E(\pi^* \leftarrow \sigma) < E(\sigma^* \leftarrow \sigma)$. Of these transitions, $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ dominate in the UV/visible region.

11.4.1
Chromophores

Although molecular orbitals involved in absorption extend over the entire molecule, it is often possible to identify a specific atom or group of atoms in the molecule as a chromophore; that is, as a functional group that acts as the dominant light-absorbing unit. A list of chromophore properties for the most common functional groups is presented in Table 11.2 (Pavia, Lampman and Kriz, 1996)

Most $\pi^* \leftarrow n$ transitions involving heteroatoms are weak because the spatial orthogonality of the n-bonding orbitals relative to the π^*-system make the transition's symmetry forbidden. Similarly, there is no overlap between σ and π orbitals, and therefore they can be considered separately. The $\pi^* \leftarrow \pi$ transitions listed in Table 11.2 are not particularly intense. However, their transition wavelengths can shift dramatically to longer wavelengths and grow in intensity (hyperchromism) with increasing degree of conjugation owing to a reduction in the HOMO–LUMO energy gap in much the same way that the energy level spacing of a one-dimensional particle in a box decreases with increasing box size. This trend can be examined in Table 11.3 for various polyenes although similar trends have been observed for many other unsaturated systems. The absorption intensity growth with conjugation reflects an increasing transition dipole that lies approximately along the direction of the π-system. The deviations evident in Table 11.3 arise because the polyene backbones are not completely delocalized but, instead, consist of alternating single

Tab. 11.2 Absorption wavelength maxima, λ_{max}, and molar absorption coefficient maxima, ε_{max}, for various transitions of different chromophores.

chromophore	λ_{max} (nm)	ε_{max} (L mol^{-1} cm^{-1})	Transition type
C−C	<180	1000	$\sigma^* \leftarrow \sigma$
C−H	<180	100	$\sigma^* \leftarrow \sigma$

$RCONH_2$	210	32	$\pi^* \leftarrow n$

and double bonds. Furthermore, the absorption $\lambda_{\max}$ and $\varepsilon(\lambda_{\max})$ are sensitive to cis–trans isomerization (Klessinger and Michl, 1995).

Substituents that increase the intensity and often the $\lambda_{\max}$ of absorption peaks when attached to a chromophore are called *auxochromes*. Woodward (1941, 1942) and Fieser, Fieser and Rajagopalan (1948) established a set of empirical rules for dienes that allow the absorption maximum of a compound to be determined for different additional chromophores present. Similar rules have also been deduced for conjugated carbonyl compounds, and mono- and di-substituted benzenes. These rules can be useful for structure determination.

A proper solvent for solution-phase UV/visible spectroscopy should be nonabsorbing at wavelengths absorbed by the solute of interest. A list of common solvents and their short wavelength transmission cutoffs is presented in Table 11.4 (Gauglitz and Vo-Dinh, 2003). While water and ethanol are good solvents for many substances, hexane and other hydrocarbons are appropriate for less polar compounds. The latter solvents also interact more weakly with the solute, allowing a finer structure to be resolved.

Tab. 11.4 Ultraviolet cutoff wavelength for various commonly used solvents.

Solvent	**Cutoff wavelength (nm)**
Hexane, C_6H_{14}	200
Ethanol, C_2H_5OH	210
Water, H_2O	210
Methanol, CH_3OH	210
Acetonitrile, CH_3CN	215
Cyclohexane, C_6H_{12}	215
Chloroform, $CHCl_3$	250
Carbon tetrachloride, CCl_4	280
Benzene, C_6H_6	280
Pyridine, C_5H_5N	310

Tab. 11.3 Absorption wavelength maxima, $\lambda_{\max}$, and molar absorption coefficient maxima, $\varepsilon_{\max}$, for various polyenes.

$H(CH{=}CH)_n H$	$\lambda_{\max}$ (nm)	ε ($L\,mol^{-1}\,cm^{-1}$)
1	162	10 000
2	217	21 000
3	258	35 000
4	296	52 000
5	335	118 000
8	415	210 000
11	470	185 000
15	547	150 000

Solvent polarity can play a role in determining the position of peak maxima in an absorption spectrum. This effect, called *solvatochromism*, arises because the HOMO and LUMO orbitals involved in a UV/visible absorption have different polarities and therefore interact differently with the solvent. Bathochromic (red) shifts result when the LUMO is stabilized in the solvent relative to the ground state. This effect is common for $\pi^* \leftarrow \pi$ transitions. Conversely, hypsochromic (blue) shifts arise when the HOMO is preferentially stabilized by the solvent. This type of shift is commonly observed for $\pi^* \leftarrow n$ transitions.

Peptide bonds have intense $\pi^* \leftarrow \pi$ transitions between 190 and 210 nm while aromatic amino acids absorb strongly between 205 and 280 nm (Table 11.5, Gauglitz and Vo-Dinh, 2003). The $\lambda_{\max}$ values for the UV absorptions of tryptophan, tyrosine and phenylalanine come between 255 and 280 nm, and are often used to determine

Tab. 11.5 Absorption wavelength maxima, λ_{max}, for various amino acid residues.

Amino acid	**Structure**	**λ_{max} (nm)**
Histidine		210
Tryptophan		220, 280
Tyrosine		195, 222, 275
L-Cysteine		235
Phenylalanine		190, 205, 255

the total protein concentration in solution. Furthermore these wavelengths tend not to degrade the sample. The phenolic chromophore on tyrosine is sensitive to the pH of the solution in that its absorption maximum shifts to the red with increasing solution acidity. Similarly, increases in the nonpolar environment will also red-shift the absorption maxima of tyrosine and tryptophan. The UV/visible spectra of these residues can therefore be used to probe the conformational differences of different protein states.

11.5
The Origin of UV/Visible Transitions in Inorganic Molecules

Transition metal complexes are known to be important in biological systems, as catalysts, as components of solar cells, as light emitters, nonlinear media, and so on. One of their most striking features is the wide variety of colors they can exhibit both as solids and in solution. The energies of the five d-orbitals for a given principal quantum number $n \geq 3$ in a free atom or ion are essentially degenerate. Upon ligation, however, the degeneracy of the d-orbital set is lifted in a manner determined by the nature of the ligands and the symmetry of the complex. Although ligand-field theory (through a group theoretical analysis) is the appropriate formalism needed to understand the nature of the molecular orbitals that arise because of coordination, the simpler crystal-field theory also provides insight into the visible absorptions of the complexes (Figgis, 1966)

Consider a ML_6 octahedral complex where M and L are the metal and ligand, respectively. In crystal-field theory, the ligands are approximated as point-negative charges although similar results can be deduced even if the ligands are neutral but dipolar. If the metal ion is placed at the origin of a coordinate system, the d_{z^2} and $d_{x^2-y^2}$ orbitals form a twofold degenerate set (with e_g symmetry) that have lobes that point along the axes directly toward the ligands, which are raised in energy by Coulombic repulsion. The remaining orbitals (d_{xy}, d_{yz}, d_{zx}) form a threefold degenerate set with t_{2g} symmetry that lies lower in energy than $\{e_g\}$ because they are orientated between the axes and therefore, do not point directly at the ligands. Ligand-field theory also predicts this splitting pattern. However, ligand-field theory shows explicitly that the e_g orbitals unlike the t_{2g} set are not pure metal d-orbitals but have ligand character as well.

The d-orbital splitting patterns for complexes of lower symmetries can be deduced by removing specific ligands, and noting if this yields a net stabilization of some of the d-orbitals relative to the others. As shown in Figure 11.4, for example, forming a square planar ML_4 complex by removing the 2 ligands orientated along the z-axis lowers the energy of the d_{z^2} orbital in the e_g set relative to $d_{x^2-y^2}$, as well as the energy of the d_{yz} and d_{xz} orbitals relative

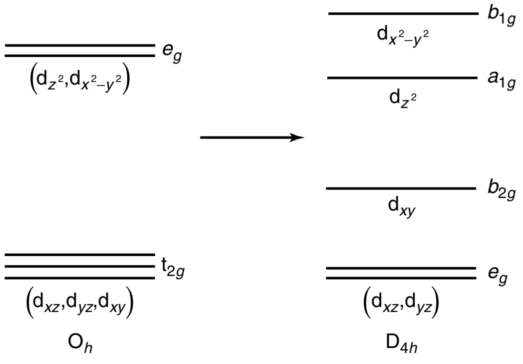

Fig. 11.4 Crystal-field splitting of the d-orbitals in an octahedral (Oh) and square planar (D_{4h}) geometry. The d-orbitals are labeled by their irreducible representations in the appropriate point group.

to d_{xy} in the t_{2g} set. Thus, the energy ordering of the d-orbitals in such a case might be $E(d_{xy}, d_{yz}) < E(d_{z^2}) < E(d_{xy}) < E(d_{x^2-y^2})$. Alternatively, the energy of d_{z^2} may even fall below that of the d_{xy}, d_{yz} pair depending on the metal ion and the nature of the ligands.

The splitting between the e_g and t_{2g} set in an octahedral complex is denoted by Δ_o and its magnitude is a strong function of the ligands making up the complex. This splitting is not trivial. For example, Δ_o for the $Ti(H_2O)_6{}^{3+}$ ion is 20 000 cm^{-1}. Ligands that yield a large Δ_o value are called *strong-field ligands* while those that result in small splittings are called *weak-field ligands*. The ligands can be empirically ordered in this regard for a given metal and geometry in a so-called spectrochemical series, which can be rationalized by considering ligand electronegativities, polarizabilities, permanent dipole moments, π-bonding characteristics, and so on. A partial list from strong field to weak field is given by

$$\begin{aligned} CO \approx CN^- &> NO_2{}^- > NCS^- > H_2O \\ &> OH^- > F^- > SCN^- > Cl^- \\ &> Br^- > I^- \end{aligned}$$

The magnitude of Δ_o also depends on the metal ion and its charge when the geometry and the ligands are held constant, although the rationale for the ordering is not as obvious. A partial spectrochemical series ranging from strong-field to weak-field ions is give by

$$\begin{aligned} Pt^{4+} &> Ir^{3+} > Rh^{3+} > Co^{3+} > Cr^{3+} \\ &> Fe^{3+} > Fe^{2+} > Co^{2+} > Ni^{2+} \\ &> Mn^{2+} \end{aligned}$$

The d-orbitals fill according to Hund's rules, which states that the terms of highest spin multiplicity lies lowest in energy. Electrons will spin-pair in the t_{2g} set before filling the e_g orbitals if the magnitude of Δ_o is large (strong-field ligands). Complexes of this sort are termed *low-spin systems*. Conversely, electrons will fill both the t_{2g} and e_g orbitals before spin-pairing if the ligands are weak field. These complexes are designated as high-spin systems.

UV visible transitions in a ML_6 complex involve promoting a d-electron from t_{2g} to e_g. Formally, however, d–d transitions are electric-dipole Laporte forbidden. However, this rule can be relaxed through vibronic coupling because the total wave function of a term includes not only an electronic component but also a vibrational normal mode. If that normal mode has the correct symmetry (in this case u-symmetry) the transition can become allowed. This is known as the *Herzberg–Teller effect*. Physically, the vibrational motion breaks the inversion symmetry of the molecule. Even so, octahedral complexes tend to have small molar absorptivities. On the other hand, the Laporte selection rule does not apply to noncentrosymmetric metal complexes geometries such as tetrahedral or trigonal bipyramidal, and so the d–d transitions tend to be stronger although the absorption coefficients are only in the range $\varepsilon \approx$ 100–200.

The strongest metal complex absorptions usually lie in the UV and can be assigned to metal–ligand charge-transfer ($g \leftrightarrow u$) transitions. If an electron is transferred from an orbital lying principally on the ligand to an orbital lying principally on the metal, or vice versa, the transitions are termed a *ligand-to-metal* or *metal-to-ligand* charge transfer, respectively. These can occur for d^0 and d^{10} systems as well as open d-shell complexes. Indeed, all polyatomic molecules exhibit such transitions, although they often come at much shorter wavelengths than the UV/visible. A charge-transfer transition, however, can occur at longer wavelengths if the metal is easily oxidized and the ligand easily reduced, or vice versa. These absorptions tend to be very intense and can often mask the crystal-field transitions. Notable in this regard are metal iodide complexes, because I^- is readily oxidized. Typical ε values for octahedral hexahalo anions range from ~600 to 60 000 (Lever, 1968). Charge-transfer transitions can be used in the analysis of ions such as Fe and Mg in biologically important systems such as hemoglobin and chlorophyll, respectively.

11.6
The Origin of UV/Visible Transitions in Solids

While transition metal crystal-field splittings are also responsible for many of the striking colors observed in mineral gemstones, the broad subject of UV/visible transitions in solids is limited here to two additional examples – semiconductors and color centers.

UV/visible radiation can excite many semiconductors from their valence band to their conduction band. These can be classified as direct or indirect (phonon-assisted) transitions. A partial list of direct band-gap transitions for some binary semiconductors, and their band gaps and absorption edges at room temperature are given in Table 11.6 (Berger, 1997).

Tab. 11.6 Electronic band gap and wavelength absorption edge for several common semiconductor solids.

Semiconductor	Band gap (eV)	λ_{edge} (nm)
ZnO	3.2	387
ZnS	2.8	443
ZnTe	2.4	517
CdS	2.4	517
HgS	2.1	590
CuCl	3.4	365
CuBr	2.9	428
CuI	2.9	428
AgI	2.9	428
BN	5.8	214
AlN	6.2	200
GaN	3.4	365
InN	2.0	605

Band gaps increase in energy (decrease in wavelength) at lower temperatures. Indirect band-gap materials tend to have shorter wavelength absorption edges. Furthermore, if defect levels are located within the band gap they can absorb light at longer wavelengths than the band edge.

Color centers are formed by first producing vacancies in a crystal lattice, usually by irradiating the material with X-rays. Electrons or holes are then trapped in the lattice defects. The number of color centers produced is a function of the irradiation time. Depending on the crystal, color centers can persist for a period of time ranging from days to years. The alkali halide crystals have been the subject of considerable scrutiny in this regard (Schulman and Compton, 1962), although defects can also be generated in minerals including diamond. In an F-center, one or more free electrons located in an anionic vacancy become trapped within the electrostatic field of the enclosure. They can therefore undergo energy level transitions by the absorption of UV/visible wavelengths, thus imparting color to the crystal. Defect electronic transitions in alkali halides have been the basis of several commercial infrared lasers (Silfvast, 1996).

11.7
Experimental Techniques for UV/Visible Absorption Spectroscopy

In addition to the sample, the basic UV/visible absorption spectrometer consists of three parts: a light source, a wavelength dispersive instrument such as a monochromater, and a detector. Each is considered separately.

11.7.1
Light Sources

The most common UV/visible light sources can be grouped into two categories: thermal sources and luminescent sources. The merits of light-emitting diodes (LEDs) and synchrotrons are also discussed (Schmidt, 2005).

11.7.1.1 Thermal Sources

Thermal sources convert electrical power into heat and emit light according to Planck's Law. The simple incandescent light bulb is the most common example. In these devices a tungsten filament is placed in an evacuated glass bulb and is resistively heated by an electric current. The resultant Planck Law temperature is typically ~2500 K. Over time, small amounts of the tungsten will vaporize from the filament, coating and blackening the bulb. This effect can be reduced by adding an inert gas to the bulb such as Ar, Kr, or Xe.

Halogens lamps essentially operate the same way as incandescent lamps except here a halogen gas (usually a bromide) is added to the bulb. This additive will react with the evaporated tungsten vapor to form a tungsten bromide compound that falls back onto the filament where it is converted to elemental tungsten. The sizes of these sources, which operate at T ~3450 K, are usually small, and therefore, make good point-light sources.

11.7.1.2 Luminescent Sources

The mechanism behind luminescent sources involves electronic excitation of atoms that emit light upon relaxation. Gas-discharge lamps are the most common devices in this group and, depending on the pressure of the device, they can operate as continuum sources (broad wavelength outputs) or as atomic line sources (specific wavelengths).

Hg lamps consist of a bulb containing an inert gas and a trace amount of mercury. When a high voltage is applied and the gas breaks down, electrons are accelerated to kinetic energies that cause the rare gas to be ionized. Ion–electron recombination excites the rare gas, which subsequently transfers its energy to the Hg atoms, which, in turn, emit light. At low pressures ($\sim 10^2$ Pa), most the light comes out at the Hg resonance line at 253.7 nm. At medium pressure ($\sim 10^5$ Pa) the output has many spectral lines, and the device usually requires higher currents to operate. At high pressures ($> 3 \times 10^6$ Pa) the spectral output consists of broad overlapping bands that extend from the UV to the near infrared. However, the flux in the red and blue–green regions of the visible spectrum is relatively small.

Xe arc lamps operate at a Planck's Law temperature of ~6000 K. They put out less radiant energy than an Hg lamp in the UV region, but more in the visible region. Their chief strength is that the spectral output is relatively smooth in the visible although there are some spectral lines in the blue and near infrared regions.

Among the best continuum UV light sources are the hydrogen lamps where emission results from the recombination reaction: $H_2 \leftarrow 2H$, at a surface. Heat conduction can be minimized in the device and the radiant energy increased by using deuterium instead of hydrogen. The emission from these sources maximizes at 290 nm. Often, the one strong atomic H or D Balmer series emission line at 486.12 or 485.99 nm, respectively, can be used for wavelength calibration.

In most spectrophotometers, two lamps are needed to cover the entire UV/visible spectral range. Typically, a D_2 lamp is used for the UV and a halogen lamp is used for the visible ranges. There is an obvious complexity to the instrumentation that will arise when one lamp is switched to the other.

11.7.1.3 Light-Emitting Diodes

LEDs are solid-state devices where the recombination of electrons and holes generates light. Depending on the semiconductor material, they can emit light between ~350 and 1550 nm. While their efficiencies and radiant energies are usually low, they have long lifetimes and are very inexpensive. White LEDs have now been developed, which operate on one of two mechanisms. The most dominant approach is to combine a 450–470-nm gallium nitride (GaN) LED with an yttrium aluminum garnet (YAG) phosphor. The blue output of the GaN LED causes the phosphor to glow white out to ~700 nm. The second method involves combining the outputs of red, green, and blue LEDs in the proper proportion to obtain white light.

11.7.1.4 Synchrotrons

Synchrotron emission from an electron storage ring provides wavelength coverage from the infrared to γ-rays. Each pulse of synchrotron light is highly polarized and short ($<10^{-10}$ seconds), and the repetition rate of the pulse train can reach 5×10^8 s^{-1}. Despite this wavelength versatility, synchrotrons are "big science" and as such, would probably not be the first choice for work in the UV/visible where cheaper tabletop sources abound. They are, however, indispensable for high-resolution spectral studies and crystallography in the X-ray region.

11.7.2
Wavelength Dispersive Instruments

Dispersive instruments spatially separate a light beam on the basis of wavelength. The simplest optic for performing this feat is a prism, usually made of quartz or glass, whose dispersive power is a function of its wavelength-dependent index of refraction $n(\lambda)$. A geometrical analysis shows that the wavelength-dependent beam deflection, δ through a prism is given by $d\delta/d\lambda = -B/H\, dn/d\lambda$, where $dn/d\lambda$ is the change in index of refraction with wavelength, B the dimension of the base of the prism, and H is the height of the incident beam.

Higher resolution dispersion can be obtained using diffraction gratings. Diffraction gratings are ruled or holographically produced substrates containing several hundred to $>10^3$ lines per millimeter. A grating gives rise to wavelength-dependent interference patterns by Bragg diffraction when illuminated. The directions of constructive interference, or intensity maxima, arise when the path differences between scattered rays are an integer multiple of the wavelength. These integers, m, are called *diffraction orders.*

Gratings can operate in transmission (slits) or in reflection (grooves), and their resolving power R is defined as

$$R = \frac{\lambda}{d\lambda} \tag{11.9}$$

R is a measure of how well it can separate two close-lying wavelengths, and is related to the number of grooves, N through

$$R = mN \tag{11.10}$$

Although the linear dispersion (spatial separation in a plane), $d\lambda/dx$, will increase with order m, at a fixed grating orientation light, for example, at 800 nm in first order, will overlap 400 nm light in second order, 266.7 nm light in third order, and so on. The different orders can be separated using filters, or, alternatively, by modifying (blazing) the shape of the grooves so that the scattered energy is concentrated primarily into one order.

Diffraction gratings are the main dispersion elements in monochromators. These instruments are used to measure the intensity of different wavelengths sequentially as a grating is rotated. The two common geometries used for UV/visible spectroscopy are the Fastie–Ebert configuration and a Czerny–Turner design.

11.7.2.1 **Fastie–Ebert Configuration**

The optical arrangement of a Fastie–Ebert spectrograph is shown in Figure 11.5. The main components are a spherical mirror and one plane diffraction grating. The entrance and exit slits of the instrument are both placed at the focal plane of the spherical mirror. Light entering the first slit and reflected off the mirror is dispersed by the grating. The

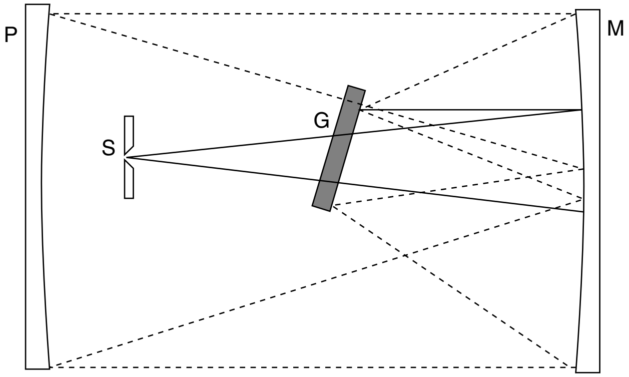

Fig. 11.5 A schematic of a Fastie–Ebert spectrograph. P, photographic plate; S, slit; G, grating; and M, concave mirror. The solid and dashed lines indicate the light path above and in line with the grating.

light is then rereflected and collimated by the spherical mirror to form an image at the exit slit. A UV/visible spectrum can be obtained by detecting the output light intensity photographically, or with a detector at the exit slit as a function of grating rotation.

11.7.2.2 **Czerny–Turner Configuration**

Czerny–Turner monochromators operate in much the same manner as the Fastie–Ebert design, in that the entrance and exit slits are fixed, and the monochromator is tuned by rotating a plane diffraction grating. The main difference is that the single spherical mirror in the former design is now replaced by two concave mirrors. This provides more flexibility in the geometry of the mirrors and can eliminate certain optical aberrations such as coma. This is also the preferred design when designing larger instruments where a single spherical mirror with good optical properties may be difficult to manufacture.

11.7.2.3 **Single-Beam Versus Double-Beam Spectrometers**

Single-beam spectrometers disperse one beam of light passed from a source; the beam is then passed through the sample and onto the detector. The measurement can be then repeated for a reference solvent. Double-beam spectrometers, on the other hand, use a split dispersed light beam that is passed through the sample and reference solvent at the same time (Skoog, 1985).

Single-beam instruments are technically simpler and often produce spectra with a better signal-to-noise ratio because the full radiant light energy of the lamp is used. However, the quality of the spectrum is also determined by the constancy of experimental conditions such as the output power of the lamp and electrical noise.

Conversely, dual-beam instrument operation compensates for lamp and electrical fluctuations, but the spectra often have poorer signal-to-noise ratios because only half the light beam is used for either the sample or the reference solvent. The instruments are also technically more sophisticated.

In general, single-beam instruments are adequate for absorbance measurements done at a fixed wavelength, while dual-beam instruments may be more appropriate for recording absorption spectra over a broad wavelength range.

11.7.3
Detectors

Many UV/visible detectors have been developed. A short survey of the most common devices is presented here.

11.7.3.1 **Photodiodes**

UV/visible light can be measured using an Si-based device known as a *reverse bias photodiode*. Here a voltage depletes the conductance at the junction of the p–n junction to nearly zero. When light falls on the depleted layer, holes and electrons are formed, which provide a current proportional to the light intensity. The equivalent quantum efficiency of a photodiode is considerably higher than that of a photomultiplier (PMT) tube (Section 5.3.2), but has a lower sensitivity because there is no signal amplification. The diode sensitivity can be increased using a p–i–n or PIN structure. Here an intrinsic (undoped) layer, i, is placed between the p- and n-doped regions, which, when illuminated, also creates hole and electrons that contribute to the photocurrent. The quantum efficiency of this arrangement is larger because the depletion layer is thicker. The output of a diode provides an indication of the impinging light energy over a time interval.

11.7.3.2 **Photomultipliers (PMTs)**

Many UV/visible detectors rely on the photoelectric effect to convert optical signals to an electrical output. Here, a material (termed a *photocathode*) with an appropriate work function will eject electrons upon illumination. Typical photocathodes are made of mixed alkalis (Table 11.7, Lytle, 1974). Under an applied voltage the elected electrons are measured as a photocurrent. The quantum efficiency of the photocathode is defined as the probability that a photon will eject an electron, and is usually less than unity.

In a PMT tube, the electrons ejected from the photocathode strike a chain of additional photoemissive electrodes, or dynodes, each at a successively higher positive potential. The first dynode will emit several electrons for each electron striking it. Those electrons cause the second dynode to emit several electrons, rapidly leading to a cascade multiplication of electrons at the end of the chain. The total gain in many devices can exceed 10^6. PMT-tube sensitivity is usually limited by their dark-current emission, but this can be almost eliminated by cooling the tube to low temperatures.

11.7.3.3 **Microchannel Plates (MCP)**

A microchannel is a small glass tube ~1-mm long, with typical inner diameters between 8 and 20 μm, whose inner surface is coated with a semiconductor material (Dereniak and Crowe, 1984). Like a dynode stage of a PMT, the inner surface will emit secondary electrons when struck by a primary electron. The gain in a channel under an applied voltage of $\approx 10^3$ V is on the order of 10^4. Microchannel plates (MCPs) are arrays of these tubes sandwiched between metal electrodes, and there can be between 10^4–10^7 microchannels per plate. The primary electrons come from a photocathode placed in front of the array. The gain can be increased to $\approx 10^7$ by placing two MCPs in series. Each channel can produce an intensified picture element

Tab. 11.7 Absorption maximum, λ_{max}, and quantum efficiency for several typical photocathode materials.

Nominal Composition of Photocathode material (response[a])	λ_{max} (nm)	Quantum efficiency (%)
Cs_8Sb (S-11)	440	16
Cs_8Sb (S-4)	400	12.4

or pixel in an imaging system or the total current can be collected and plotted as a function of wavelength to yield a spectrum.

11.7.3.4 Charge Coupled Devices (CCD)

Although charge coupled devices (CCDs) were first invented as a computer memory circuit, they have become prevalent as light detectors in imaging applications. CCD cameras are either one-dimensional or two-dimensional pixel arrays of metal oxide semiconducting capacitors (based on Si) (Eastman Kodak, 2001). The number of electrons and holes produced within a pixel by an incident light beam is linearly proportional to the light level and exposure time at that location. There is also a nonlinear dependence on wavelength because of a changing penetration depth into the photocapacitor. When a voltage is applied to the pixel, a potential well is formed, which "collects," or integrates, the charge. The charge formed in each pixel is then transferred serially within the silicon substrate using a series of voltage gates, converted to a voltage signal, amplified, and then processed (by other equipment) to give an image. These devices can be employed in an absorption spectrometer by removing the exit slit and imaging the output off the diffraction grating onto a pixel array.

Overall, PMTs have excellent sensitivity, linearity, and dynamic range for measuring instantaneous light powers, and are reasonably priced. MCPs and CCDs are also excellent detectors with the added advantage that they can be used for spatial imaging. While these latter devices have recently become more affordable, they are usually more expensive than most PMTs.

11.8
Laser-Based Techniques

Although lasers have had a profound impact on the field of spectroscopy, they are surprisingly poorly suited for direct absorption measurements in the UV/visible range. The reason for this is that a direct absorption measurement entails measuring a small decrease in the output of an intense but usually fluctuating monochromatic source due to sample absorption. Nevertheless, several powerful laser-based methods have been developed, which circumvent these difficulties and allow UV/visible absorption spectra to be recorded particularly for gas-phase species.

11.8.1
Fluorescence Excitation Spectroscopy

Laser-induced fluorescence involves detecting optical emission from a sample that has been excited by the absorption of laser radiation. As shown in Figure 11.6, fluorescence excitation spectra can be recorded by measuring the total undispersed laser-induced emission as a function of the tunable exciting light wavelength using an optical detector such as a PMT. It can be shown that if the light collection efficiency and fluorescence quantum yield are independent of wavelength, the resultant spectrum is equivalent to an absorption spectrum (Lipson and Shi, 2002). This technique is considerably more sensitive than direct absorption because, in principle, optical detection is measured against a zero-light background. Nevertheless, care must be taken to eliminate scattered light, which can be orders of magnitude more intense than the fluorescence. Spatial pinhole filters before the PMT can

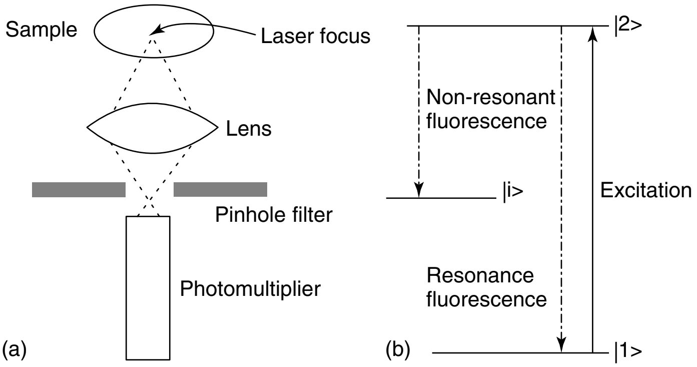

Fig. 11.6 (a) Schematic diagram of a typical experimental arrangement required to record laser-induced fluorescence excitation spectra. help in this regard. Sub-Doppler resolution gas-phase spectra can be obtained by sample delivery in a molecular beam or a supersonic jet expansion (Smalley, Wharton and Levy, 1977), and detecting fluorescence in a direction perpendicular to the gas flow.

11.8.2
Excitation Spectroscopy with Mass Detection

Not every molecule will fluoresce when excited. In such cases, one can use one or more laser beams to ionize the molecule of interest for detection in a time-of-flight mass spectrometer (Ashfold, 1998). The process of resonant two-photon ionization (R2PI) is described by

$$\mathrm{M}\xrightarrow{\mathrm{h}\nu}\mathrm{M}^*\xrightarrow{\mathrm{h}\nu'}\mathrm{M}^+ + \mathrm{e}^- \qquad (11.11)$$

where the first photon at frequency ν resonantly excites a molecule M while a second photon at frequency ν' ionizes the excited molecule. The ionization reaction is a one-colour process if the photons involved come from the same laser and have the same frequency. If photons are used from different lasers, and ν and ν' are different, the process is called a *two-colour ionization*. Mass selected, vibronically resolved excited-state spectra can be obtained by varying the laser excitation wavelength while monitoring the molecular mass peak. R2PI is the simplest variant of $(m + n')$ resonance enhanced multiphoton ionization (REMPI) where m and n corresponds to the number of photons required to excite the molecule and ionize the excited state, respectively, and the prime indicates that the ionizing photons come from a laser different from the excitation source.

If the molecule predissociates or undergoes some photochemical reaction, it is possible to monitor the mass of a daughter fragment ion produced to obtain an absorption spectrum of the parent. This general approach of detecting a consequence of absorption to obtain the spectrum of a parent molecule is called *action spectroscopy*.

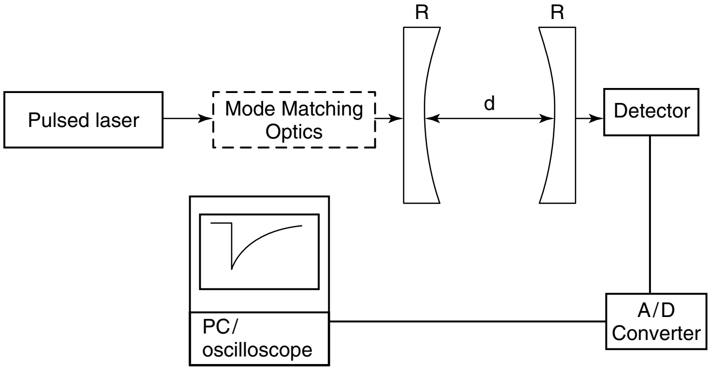

Fig. 11.7 Schematic of a typical cavity ring-down spectroscopy setup. *R* is the reflectivity of the mirrors making up the cavity of length *d*. The mode-matching optics may be optional.

11.8.3
Cavity Ring-Down Spectroscopy

Absorption spectra in cavity ring-down spectroscopy are obtained by measuring the rate of decay of light intensity inside a high-*Q* resonator (Figure 11.7) (Paldus and Kachanov, 2005). The intensity of light injected into the cavity will decay exponentially with a rate constant, $R(\lambda)$, that depends on the optical losses in the cavity.

The optical loss in an empty cavity, $L_{\text{cav}}(\lambda)$, is the sum of the round-trip scattering losses, $L_{\text{scat}}(\lambda)$ and the round-trip transmission losses through the high-reflectivity mirrors, $L_{\text{trans}}(\lambda)$. When a sample is added to the cavity, there is an additional loss due to absorption, $A(\lambda)$, which is governed by Beer's Law (Eq. 11.2). These factors are related to $R(\lambda)$ through

$$R(\lambda) = \frac{L_{\text{cav}}}{t_{\text{rt}}} + c\varepsilon(\lambda)[C] \qquad (11.12)$$

where $t_{\text{rt}} = \ell_{\text{rt}}/c$ is the photon round-trip transit time in the resonator, and ℓ_{rt} and c are the cavity round-trip length and the speed of light, respectively. $R(\lambda)^{-1}$ is called the *cavity ring-down time*. Measuring $R(\lambda)$ from the exponential intensity decay provides an accurate measurement of $\varepsilon(\lambda)$. An absorption spectrum is acquired by measuring $\varepsilon(\lambda)$ as a function of exciting laser wavelength, λ.

If high-reflectivity mirrors are used (>99.99%) that have low scattering losses (<0.001%), the effective total path length, which is determined by the average photon lifetime in the cavity, can be enhanced by factors of $>10^4$. This makes cavity ring-down spectroscopy very sensitive, even relative to setups that employ a multipass configuration. Cavity ring-down measurements are independent of the initial light intensity inside the cavity and the path length. Both pulsed and continuous wave sources can be used, and the technique is chemically specific because of the narrow linewidths available for many laser sources.

12.1
Introduction

The Earth, our home, is a blue planet. Color abounds from the blue sky, the striking sunsets, and the lush green of the rain forests to the bright reds and oranges of the fall foliage. Since prehistoric times man has used color to brighten life. Ancient civilizations created brightly dyed fabrics and decorated pottery. Michelangelo, Renoir, and Picasso are among the master artists who used color to enhance their art. Imagine how dull the world would be without color. Until recently, products were available in a limited variety of colors. You could buy a Model T automobile in any color you wanted as long as it was black. However, times have changed and today's consumers demand products in a wide variety of colors. Modern materials provide us with products in a multitude of colors that could only have been dreamt of in the past. Materials colored with metallic and interference pigments change colors as the illuminating and viewing conditions change. Materials colored with thermochromic pigments change color with temperature. The use of fluorescent pigments results in materials with eye-popping colors.

Scientist and technicians use colorimetry, the measurement of color, to ensure that consumers get the colors they expect consistently over time. In colorimetry, we try to simulate the human experience to quantify and control color.

In this chapter we consider color perception, the mathematics of simulating the perception of color, the color difference between two objects, and the instruments used to measure color. Several special measurement cases are also discussed.

12.2
Color Perception

In conversation we speak about a yellow school bus or a green traffic light as if the object's color was an intrinsic property of the object. Color, however, is a perception. Light falls upon an object. The object reflects and/or transmits that light depending upon the pigments used to color the object. The reflected and/or transmitted light enters the observer's eyes and the brain translates the resulting nerve impulses into the perception of color. Color is but one aspect of an object's appearance. Gloss and texture are two other important aspects of appearance. Color perception

ISBN: 978-3-527-40773-6

is an extremely complex phenomenon. For example, the background on which an object is viewed can have a major effect on the perceived color of that object. The ambient light to which the eye becomes adapted also influences the color of objects. When we speak of color in the remainder of this chapter, we are speaking of the perception of a single, independent color by an individual with normal color vision (99.5% of women and 92% of men).

Color is three dimensional; hence, three terms are needed to describe a specific color. Typically, colors are described with reference to their lightness, chroma, and hue. Hue would be the general name for a color, for example, blue, green, yellow, red, and purple. Colorists think of hue as a circular dimension around a central axis of neutral (white to black) colors. Lightness is the dimension used to distinguish among white, gray, and black. Pure white would approach the highest possible lightness, whereas jet black would approach the lowest possible lightness. Grays range between white and black. Lightness can distinguish between colors with distinctive hues, for example, the difference between a light blue and a dark blue. Chroma is a more difficult concept. Chroma distinguishes a color's colorfulness or difference from a neutral gray. This would be the difference between a brick red and a red cherry. If the brick and the cherry have the same hue (the brick is neither yellower nor bluer than the cherry) and the same lightness, then the brick would be described as being a low-chroma red and the cherry would be described as being a high-chroma red. The terms dull (low chroma) and saturated (high chroma) are sometimes applied to chroma. Colors that differ only in lightness (white to gray to black) are called *achromatic colors*. Those colors with perceptible hue and chroma are called *chromatic colors*.

12.2.1
Color Constancy and Metamerism

The color of an object may change as the lighting conditions change. This change in color is called *flare*. For example, a red ball may look bluer outside in daylight than in a living room lighted with incandescent lamps. We would say that the ball flared red when illuminated by incandescent light. The magnitude of the change is dependent upon the pigments used to color the object. Colorists judge the effect of different illuminating conditions using industrial light booths (cabinets). Most light booths provide a simulated daylight lamp, an incandescent lamp, and a fluorescent lamp. Some light booths also have ultraviolet lamps for determining whether an object is fluorescent. The eye will try to adjust to different lamps so that they appear to be "white" (chromatic adaptation) when looked at directly.

In most industrial situations, it is preferred to keep an object's color the same as the lamp is changed. That effect is called *color constancy*. Changes in color resulting from changes in the light source can cause some very undesirable results. For example, two yellow objects are colored using different pigments but have the same color when illuminated by a simulated daylight lamp. When an incandescent lamp is used to illuminate the two objects, one flares green and the other flares red. The colors of the two objects no longer match. This effect is called *metamerism*, and we describe the two objects as being metameric to one another. Metamerism is a major problem for industrial color matchers, particularly when trying to match a target color obtained in one material (such as a dyed bath towel) to that made in a different material (such as a plastic toothbrush holder). Can you imagine buying a suit whose jacket only matches the pants when illuminated by incandescent light?

12.3
The CIE System of Colorimetry

The Commission Internationale de l'Éclairage (International Commission of Illumination), which is usually referred to by its French initials – CIE, is an organization of countries that is concerned with light and its measurement. The scientists and engineers whose countries were members of the CIE did the pioneering work in color measurements. The CIE, by the consent of all its member countries, specifies the basic standards for use in colorimetry. The first major recommendations regarding colorimetric standards were made by the CIE in 1931 and formed the basis of modern colorimetry. Since then many additional recommendations have been made by the CIE and adopted in the field of color measurement (CIE, 2004)

12.3.1
Light and Light Sources

12.3.1.1 Visible Light

The Earth is constantly bombarded with electromagnetic radiations. This includes cosmic rays, gamma rays, visible light, and radio lights. Visible light makes up only a small portion of the electromagnetic spectrum. Visible light is the electromagnetic energy that stimulates the cells in the human eye. In colorimetry, we characterize visible light by its wavelength in nanometers (nm). The CIE considers visible light to range from 360 to 830 nm. Not everybody can perceive light throughout that entire wavelength range. Most humans can perceive light between 400 and 700 nm and many color measuring instruments can only measure light within that more restrictive wavelength range.

Each of the wavelengths (or a narrow band of wavelengths) of light is perceived as a color. The wavelengths between 360 and 500 nm will appear to be shades of violet and blue; the wavelengths between 500 and 580 nm will appear to be shades of green; and the wavelengths between 580 and 830 nm will appear to move from shades of yellow to shades of orange to shades of red.

A light source emitting a broad band of wavelengths may appear to have color even though the eye adapts and tries to make it appear white. The sun appears red, yellow, or white depending upon the time of day and the scattering of the light by particles in the atmosphere. An incandescent bulb will be described as yellow, and fluorescent lamps will usually look white. If you take a walk around dusk, your eyes will adapt to the bluish color of daylight. If you pass a house with a window to an interior room lit by an incandescent lamp, you will immediately notice how yellow the incandescent lamp is compared to outside daylight.

If you heat a block of pure carbon, it will change color from black to yellow, to white, and then blue as the temperature increases. The carbon block can be heated until its color matches the color of the light source. The temperature of the carbon block (in kelvin, K) when its color matches the light source would be the color temperature of the light source. An incandescent light bulb that appears to be yellow has a color temperature of about 2850 K, whereas north sky daylight has a color temperature of about 7500 K. If a match between the heated carbon and the light source cannot be made, the temperature of the closest color to the light source would be used and is called the *correlated color temperature.* In conversation, and often in writing, many people do not distinguish between the color temperature and the correlated color temperature and use the terms interchangeably.

A light source can be characterized by its spectral power distribution (SPD), which is the relative power emitted by the light source at each wavelength of interest. Some light sources emit radiation outside of the region of visible light. Wavelengths of interest for those light sources may extend below the 360 nm visible range into the ultraviolet region and above the 830 nm visible range into the infrared region.

12.3.1.2 **Standard Light Sources and Illuminants**

For hundreds of years, north sky daylight has been the favorite light source for color matchers. Unfortunately, the use of natural daylight limits the time available for color matching. In our modern world, teams of color matchers may have to work round the clock to keep up with the demands for their products. Natural daylight is not constant and changes during the course of the day. In the morning, natural daylight will have a color temperature of about 3000 K and at noontime about 5000 K. Average daylight has a color temperature of 6500 K and north sky daylight has a color temperature of 7500 K. Average daylight and north sky daylight would appear bluish if it were not for the chromatic adaptation of the eye, which makes daylight appear to be white. The bluish cast of daylight can sometimes be seen in photographs.

Recognizing the problem with natural daylight, the CIE defined three reproducible light sources for use in colorimetry. CIE source A was a tungsten filament light bulb with a color temperature of 2854 K. CIE sources B and C were created by filtering the light from source A. Source B approximated noon sunlight and source C approximated average daylight. Source B is no longer recommended for colorimetry.

A distinction must be made between the terms *light source* and *illuminant.* A light source is a real entity that can be turned on and off to illuminate objects. An illuminant is an SPD representing a light source. CIE standard illuminants A, B, and C were created by measuring the SPDs of standard sources A, B, and C. Illuminants are used in colorimetric calculations.

Although CIE source C is an approximation to average daylight, there are some significant differences. Since source C is based on an incandescent lamp, it does not have much power in the blue and ultraviolet regions of the spectrum, whereas natural daylight does. When measuring fluorescent materials, it is important to simulate the amount of ultraviolet radiation in natural daylight.

In 1968, the CIE adopted the D series of standard illuminants duplicating the SPDs of various phases of natural daylight (CIE, 2004; ASTM 308). The name of the various D illuminants is based upon their correlated color temperature, such as D50 (5000 K) and D65 (6500 K).

D65 is commonly used in the textile, paint, and plastics industries, whereas D50 is typically used in the graphic arts. Very few real light sources simulate any of the D illuminants satisfactorily; hence, the CIE recommended procedures for assigning the quality of daylight simulators (CIE, 2004).

Fluorescent lamps are widely used in stores and offices. As a result, the CIE defined a series of fluorescent (F) illuminants to represent commonly used fluorescent lamps (CIE, 2004). F illuminants are grouped according to the types of phosphors used in the manufacture of lamps. F1–F6 represent the traditional fluorescent lamps, which use two semibroadband emissions of antimony and manganese activations in a calcium halo-phosphate phosphor. F2 represents a typical cool white fluorescent lamp and is the most used of the F illuminants. F7–F9 represent the "broad-band" group of fluorescent lamps, which are made using multiple phosphors in order to have better color-rendering properties than the standard group. Color rendering is the ability of the illuminant to keep a group of colors the same as the reference illuminant, typically D65. F10–F12 represent the three narrow-band group of fluorescent lamps, which were developed to save energy and still had excellent color-rendering properties. Each of these illuminants has a narrow-band emission in the red, green, and blue wavelength regions. Rare-earth phosphors are used to make lamps representing these illuminants. Illuminants D65, A, and F2 are illustrated in Figure 12.1 and illuminants F2 and F11 are illustrated in Figure 12.2.

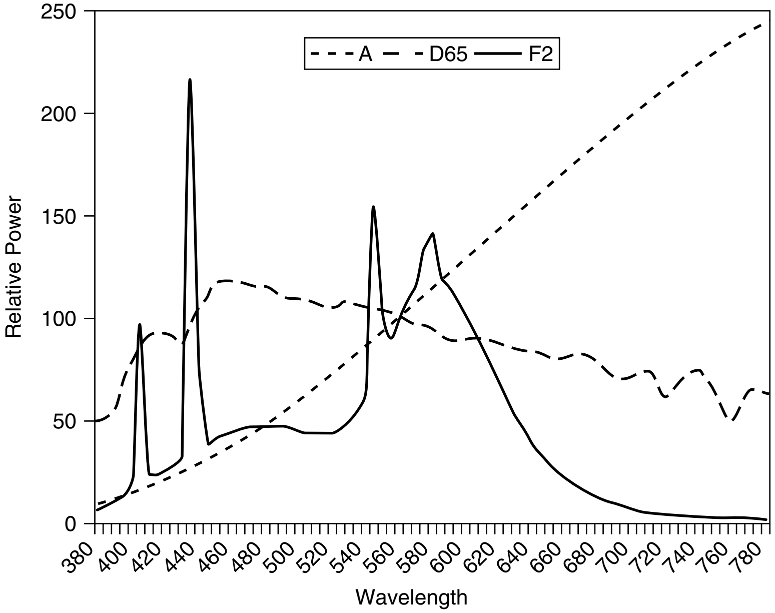

Fig. 12.1 The relative spectral power distribution of CIE standard illuminants A, D65, and F2. The curves are for shape comparison and normalized so that they have a value of 100.00 at 560 nm.

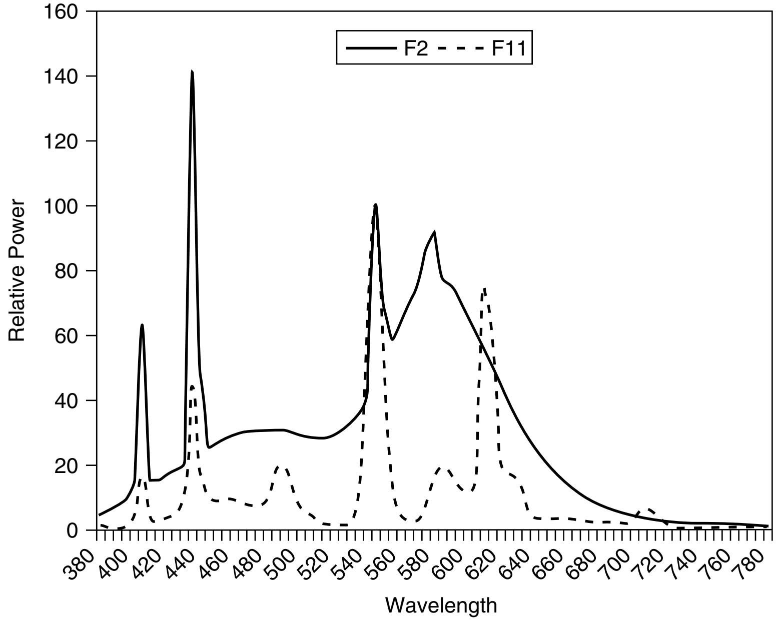

Fig. 12.2 The relative spectral power distribution of CIE standard illuminants F2 and F11. The curves are for shape comparison and normalized so that they have a value of 100 at 540 nm.

12.3.1.3 **Color-Matching Booths**

Commercial color matching takes place during the day and at night. Daylight is not available at night and other light sources are required to determine metamerism. It is essential that the visual evaluation of color be done under standardized illumination, such as that provided by a color-matching light booth. The light sources in the booth attempt to duplicate the CIE standard illuminants. Some manufacturers do better than others and it is extremely difficult to come close to achieving the SPD of real daylight with an artificial light source. However, a carefully manufactured and maintained light booth permits a colorist to make a visual evaluation of color with the confidence that the illumination stays constant over time.

12.3.2
Characterizing Objects

When light illuminates an object, the object will absorb, reflect, emit, and/or transmit that light. The events that take place depend upon the object and the pigments used to color it. If all of the light is reflected from an object, it will appear white. If all of the light is transmitted through an object, it will appear clear. If all of the light is absorbed by an object, it will appear black. Most objects will selectively absorb some wavelengths of light and will reflect or transmit the other wavelengths. The color of the object depends upon which wavelengths are absorbed and which are reflected or transmitted. Fluorescent objects absorb some wavelengths of light and then (in addition to reflection or transmission) emit light at longer wavelengths. Phosphorescent objects will emit light after the initial light no longer illuminates them and will "glow in the dark".

In colorimetry, we represent objects by their spectral reflectance or transmittance curves, the amount of light reflected or transmitted at each wavelength of the visible spectrum. The reflectance of an object is the ratio of reflected radiant flux to that of the incident flux. In common usage, the term *reflectance* is often used as an abbreviation for the term *reflectance factor*. The reflectance factor is the ratio of the intensity of reflected radiant energy to that reflected from the perfect reflecting diffuser under the same geometric and spectral conditions of measurement. The perfect reflecting diffuser is defined as an ideal reflecting surface that neither absorbs nor transmits light, but reflects diffusely, with the radiance of the reflecting surface being the same for all reflecting angles, regardless of the angular distribution of the incident light (ASTM E284). The perfect reflecting diffuser is the theoretical standard used for the instrumental measurement of reflectance. For the remainder of this chapter, we generally refer to the reflectance of an object since the calculations do not distinguish between the two. The transmittance of an object is the ratio of transmitted flux to that of the incident flux under specified geometric and spectral conditions (ASTM E284).

Figure 12.3 shows the spectral reflectance curves of black ink and of a white ceramic tile. Figure 12.4 shows the spectral reflectance of a blue ink, a green ink, and a red ink. Black (and gray) objects absorb all of the wavelengths of light. A perfect white would reflect all of

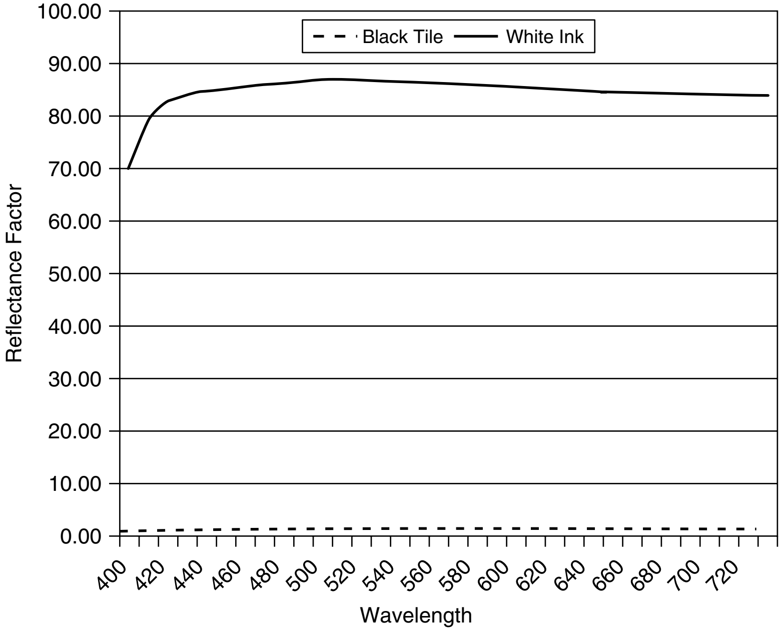

Fig. 12.3 The spectral reflectance factor curves of black ink and of a white tile.

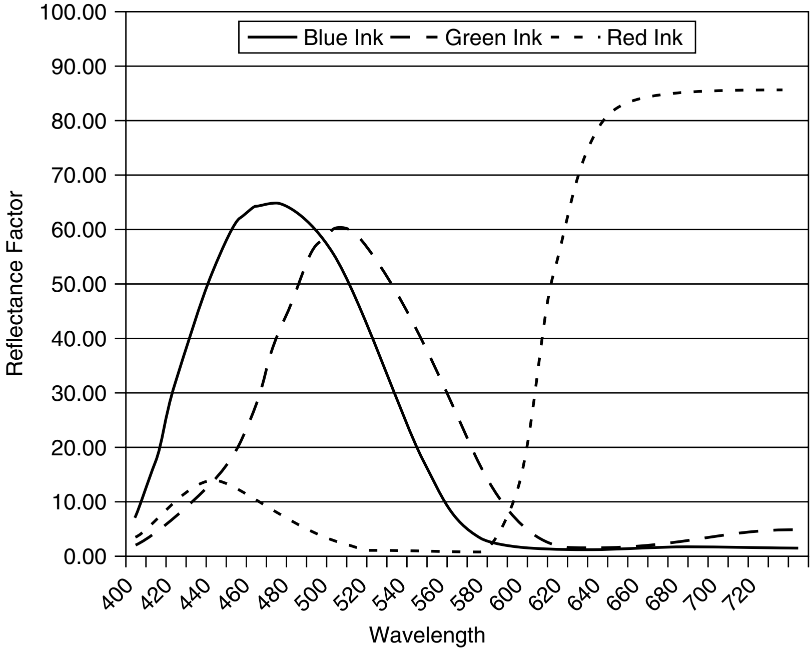

Fig. 12.4 The spectral reflectance factor curves of a blue ink, a green ink, and a red ink.

the wavelengths of light, but white objects in the real world are never perfect and will have some absorption. Many white objects have significant absorption below about 420 nm because they are colored with rutile titanium dioxide, a white pigment that absorbs strongly in that region of the spectrum. Blue objects absorb the green and red wavelengths of light, green objects absorb the blue and red wavelengths of light, and red objects absorb the blue and green wavelengths of light.

A spectrophotometer is used to measure the reflectance or transmittance factor of an object as a function of wavelength. The measured reflectance or transmittance factor of an object depends on the instrument used to make the measurements and the conditions under which the measurements are made. Several standard measuring geometries were developed for colorimetry by the CIE. These geometries are discussed in greater detail later in this chapter.

12.3.3
The Standard Observers

12.3.3.1 The Eye and Color Vision

The human eye is much like a camera. The lens images the scene on the light-sensitive retina. Two types of receptors, rods and cones, in the retina absorb a portion of the incident light and generate a signal, which is processed and interpreted by the brain. Rods detect small amounts of light and are responsible for night vision. They are not sensitive to color and are inactive at higher light levels. Cones have a much lower sensitivity to light but become active at daytime light levels. There are three types of cones called *S*, *M*, and *L*. S cones are sensitive to the short wavelengths of light, M cones are sensitive to the medium wavelengths of light, and L cones are sensitive to the long wavelengths of light. Although the spectral sensitivities of the cones slightly overlap, they are sensitive to wavelengths that roughly correspond to blue, green, and red. The cones reduce the entire spectrum of light into three signals. The distribution of rods and cones varies throughout the retina, with the cones distributed most densely at the center of the eye in an area called the *fovea*. Light triggers impulses from the cone cells that are either subtracted or added to create the black-white, red-green, or yellow-blue signals that are sent to the brain. These opponent signals travel to the brain via the optic nerve where they are interpreted as a colored image.

Most modern theories of color vision combine impulses from the rods and the three cone receptors of the eye into opponent color signals in the brain. So far, a theory of color vision that accounts for all the effects related to color perception has not been proposed.

12.3.3.2 Flare and Metamerism

Flare occurs when an object illuminated by one light source produces a different set of opponent signals than when that object is illuminated by a different light source.

The color of two objects matches when each object produces the same opponent signals. Since the cones in the eye reduce the spectrum into three signals, the two objects do not have to have the same spectral reflectance distribution to produce the same opponent signals. Metamerism occurs when the two objects have different spectral reflectance distributions but produce the same opponent signals when illuminated by one light source but produce different opponent signals when illuminated by a different light source.

12.3.3.3 Characterizing Observers

Since all color vision results from the opponent signals of the cones, shining combinations of red, green, and blue lights on the cones can produce all the colors. This was the principle used to characterize the two CIE Standard Observers.

If a single wavelength (or very narrow band of wavelengths) of light from the visible spectrum is projected upon one half of a screen, an observer should be able to match the perceived color by varying the intensities of a red, a green, and a blue light projected on the other half of the screen as shown in Figure 12.5. The amounts of each

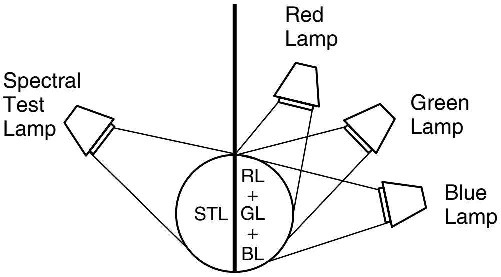

Fig. 12.5 Matching spectral colors with combinations of red, green, and blue lights.

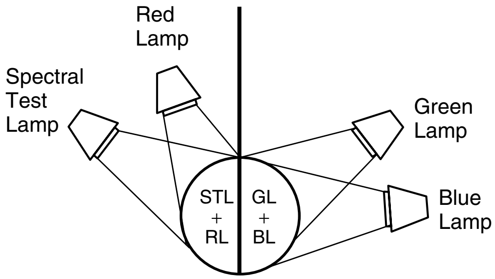

Fig. 12.6 Some spectral colors could not be matched using the combinations of red, green, and blue lights so that one of the lights had to be moved to make a match.

the three lights needed to match the spectral color are called *color-matching functions*. Observers are characterized by determining their color-matching functions for each wavelength of the visible spectrum.

Ideally, the red, green, and blue lights used in these experiments should match the responses of the three cones; unfortunately, they do not. As a result, some of the spectral colors could not be matched using combinations of real lights. When this occurred, one of the three matching lights was moved so that it illuminated the same side of the screen as the spectral color and could then be matched with the remaining two lights as shown in Figure 12.6. Moving a matching lamp so that it illuminates the same side of the observer's field of view as the test lamp results in a negative color-matching function. To avoid using negative numbers in the colorimetric calculations, the color-vision scientists created three "imaginary" lights, X, Y, and Z, to replace the real red, green, and blue lights used in the experiment. The three sets of color-matching functions (one for each light) were transformed mathematically in three sets of color-matching functions, $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$, that are always positive numbers. The symbol λ is used to indicate that the color-matching functions are wavelength dependent.

In the experiments that resulted in the 1931 CIE 2° Standard Observer, a group of observers viewed a circular field that covered 2° of their visual field, which is about the size of a dime viewed at 18 inches. Most of the cones are contained within this field of view. A 2° field of view is similar to that used to observe signal lights, flares, and other small objects.

Often a color is viewed using a much larger field of view. For example, industrial color matchers may often use samples that are at least 4 × 6 inches. Rods and the distribution of cones affect the perception of these colors. In 1964, the CIE recommended the CIE 1964 Supplemental Standard Observer. The experiments that resulted in the 1964 CIE 10° Standard Observer were based on observers viewing a circular field that covered 10° of their visual field, which is about the size of a 3-in. circle at 18 in. The three sets of color-matching functions for the CIE 10° Standard Observer are designated $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, and $\bar{z}_{10}(\lambda)$ and are shown in Figure 12.7.

Since the two CIE Standard Observers were based on averaging the color-matching functions of a number of observers, it is unlikely that they will be the same as any single observer. The differences from the CIE Standard Observer usually do not present a

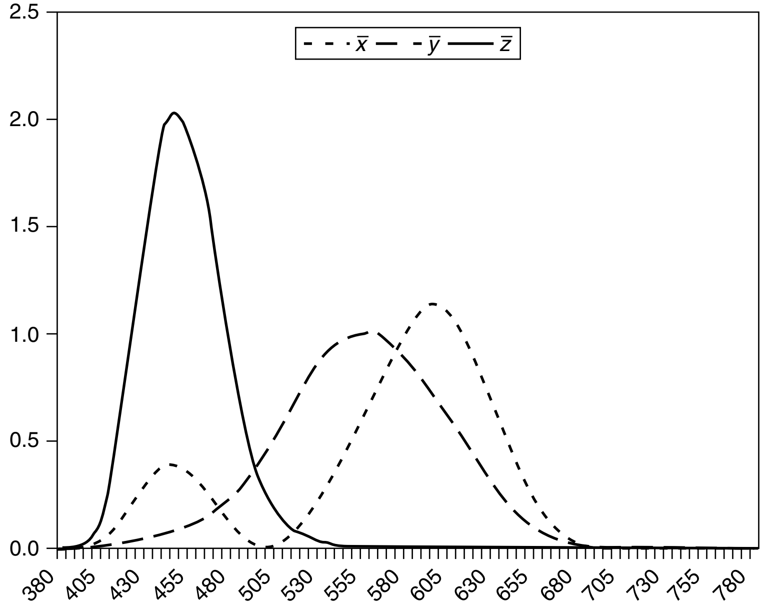

Fig. 12.7 The CIE color-matching functions for the 10° standard observer.

problem. However, they can affect the evaluation of highly metameric samples.

12.3.3.4 **Calculating Tristimulus Values**

Tristimulus values are the amounts of the X, Y, and Z lights needed to match a color. Each tristimulus value is calculated by finding the integral of the product of the spectral power distribution of the illuminant, $S(\lambda)$, the reflectance (or transmittance) of the object, $R(\lambda)$, and the appropriate color-matching function of the observer over the visible wavelength region as shown in Figure 12.8. The integral is approximated by taking the sum of those products at 1-nm intervals from 360 to 830 nm and then normalizing the sum as shown in Eqs (12.1)–(12.4). For transmitting objects substitute the transmittance factor, $T(\lambda)$, for the reflectance factor $R(\lambda)$. The factor k normalizes Y so that it is equal to 100.00 for the perfect reflecting diffuser or perfect transmitter, that is, $R(\lambda)$ or $T(\lambda)$ is equal to 1.00 for all wavelengths of the visible spectrum:

$$X = k\sum S(\lambda)R(\lambda)\bar{x}(\lambda) \tag{12.1}$$

$$Y = k\sum S(\lambda)R(\lambda)\bar{y}(\lambda) \tag{12.2}$$

$$Z = k\sum S(\lambda)R(\lambda)\bar{z}(\lambda) \tag{12.3}$$

$$k = \frac{100}{\sum S(\lambda)\bar{y}(\lambda)} \tag{12.4}$$

Reflectance and transmittance factors are often displayed as percentages ranging from 0.00 to 100.00. When calculating tristimulus values, the reflectance and transmittance factors should be expressed as a decimal ranging from 0.00 to 1.00. The above-mentioned summations are also valid for reflectance or transmittance measurements made at 5 nm intervals.

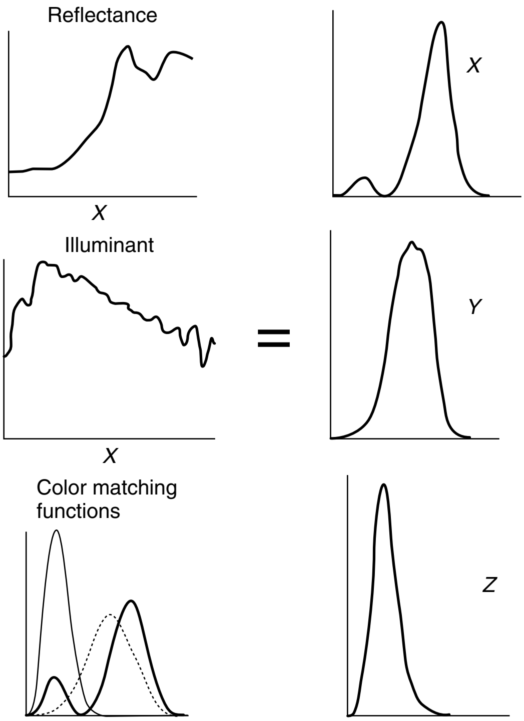

Fig. 12.8 Calculating the tristimulus values of a color.

Most commercial spectrophotometers designed for color measurement measure reflectance or transmittance factor at 10 nm intervals and some instruments measure at 20 nm intervals. Tristimulus values cannot be correctly calculated by only using the table values at 10 or 20 nm intervals. To facilitate the calculation of tristimulus factors from measurements made at 10 and 20 nm intervals, tables of normalized weighting factors, $W_x(\lambda)$, $W_y(\lambda)$, and $W_z(\lambda)$, have been published by the ASTM (ASTM 308). Weighting factors are derived from the combination of the illuminant and observer data along with other adjustments based on the wavelength interval and range selected. The tristimulus values are computed by summing the product of the weighting factor and the reflectance at the same wavelength as indicated in Eqs (12.5)–(12.7):

$$X = \sum W_X(\lambda)R(\lambda) \tag{12.5}$$

$$Y = \sum W_Y(\lambda)R(\lambda) \tag{12.6}$$

$$Z = \sum W_Z(\lambda)R(\lambda) \tag{12.7}$$

12.3.3.5 **Chromaticity Coordinates and Chromaticity Diagrams**

Most people cannot visualize a color based upon its tristimulus values. Thus, it is very useful to be able to make a graph to help visualize colors and their relationship with other colors, such as a standard and a batch. Graphing tristimulus values would require a three-dimensional plot that is very difficult to make. Separating a color into two components, its lightness and its chromaticity, allows for

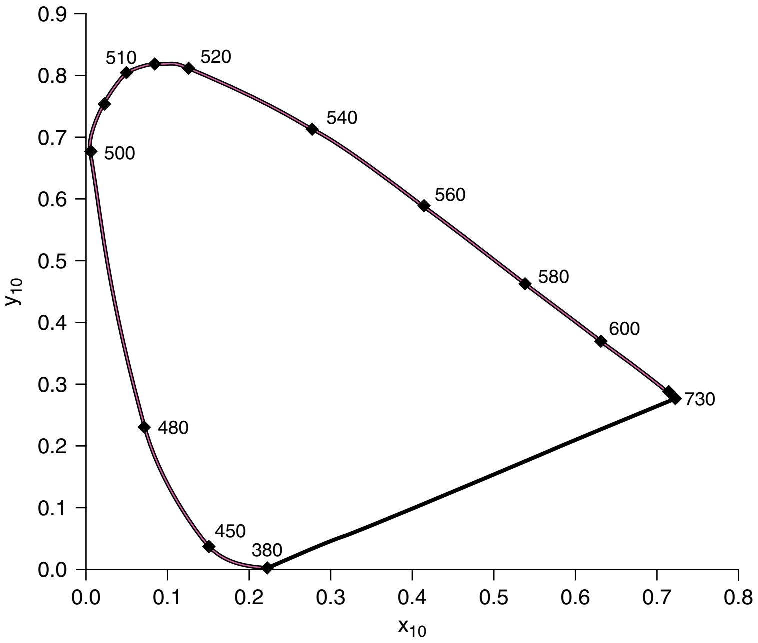

Fig. 12.9 The CIE 1964 chromaticity diagram.

a two-dimensional plot. A color's chromaticity is made up of its hue and chroma. The Y tristimulus value defines the color's lightness. The color's chromaticity coordinates, x and y, are calculated from the tristimulus values as shown in Eqs (12.8) and (12.9):

$$x = \frac{X}{X+Y+Z} \tag{12.8}$$

$$y = \frac{Y}{X+Y+Z} \tag{12.9}$$

A chromaticity diagram based on the 1964 Standard Observer is shown in Figure 12.9. The horseshoe shape contains the chromaticities of the wavelengths of the visible spectrum. The nonspectral purples are created by mixing blue light with a wavelength of 380 nm and red light with a wavelength of 780 nm. These colors fall on the straight line connecting the ends of the horseshoe.

Chromaticity diagrams are very useful for people working with colored lights and phosphors. Mixtures of two lights or phosphors will fall on the line connecting the chromaticities of each at a position predicted by the relative luminance of each light in the mixture. Plotting the chromaticities of accepted batches relative to the standard color helps define industrial color tolerances (ASTM 3134).

12.4
Color Spaces

12.4.1
The Munsell Color Space

Albert Munsell, an artist and educator, developed a visually uniform color space in the early 1900s. Munsell's system had three coordinates – hue, value, and chroma.

Value is an artist's term for lightness. A perfect black would have a value of 0, and a perfect white would have a value of 10. Each step (0–1, 1–2, 3–4,. . ., 9–10) appears to be equally different in lightness.

Munsell defined a hue circle consisting of 10 hues (red, R; yellow-red, YR; yellow, Y; green-yellow, GY; green, G; blue-green, BY; blue, B; purple-blue, PB; purple, P; and red-purple, RP). Each pair of adjacent hues in the hue circle will appear to have the same color difference as any other pair of adjacent hues in the circle when the samples have the same lightness and same chroma.

Chroma would designate a color's distance from the central neutral axis. When Munsell created his system, he used his brightest vermilion pigment to anchor the chroma at 10. Colors can have chromas greater than 10. Munsell created an atlas to exemplify his system. In his first atlas, he divided the chroma scale in visually equal steps of 2.0 chroma units.

On a perfect, visually uniform chromaticity diagram, the Munsell hue circle would plot as a perfect circle.

12.4.2
The 1976 CIE *L*a*b** (CIELAB) Color Space

Figure 12.10 illustrates a Munsell hue circle at a value of 5 and a chroma of 8 plotted on the 1931 CIE chromaticity diagram. The hue circle looks more like a pear than a circle. The members of the CIE wanted a more uniform color space than either the 1931 space or the 1964 color space. Work in the late 1960s and early 1970s resulted in the CIE 1976 $L^*a^*b^*$ (CIELAB) color space (CIE, 2004). CIELAB has gained wide acceptance in industry.

CIELAB is an opponent-type color space. Values for the lightness axis L^*,

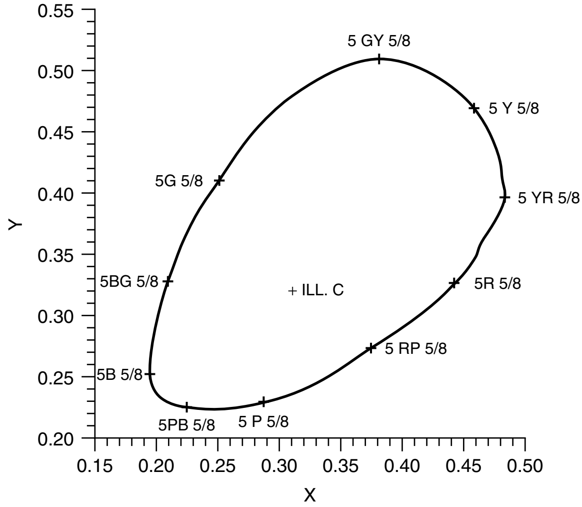

Fig. 12.10 The Munsell hue circle using the 1931 CIE chromaticity coordinates.

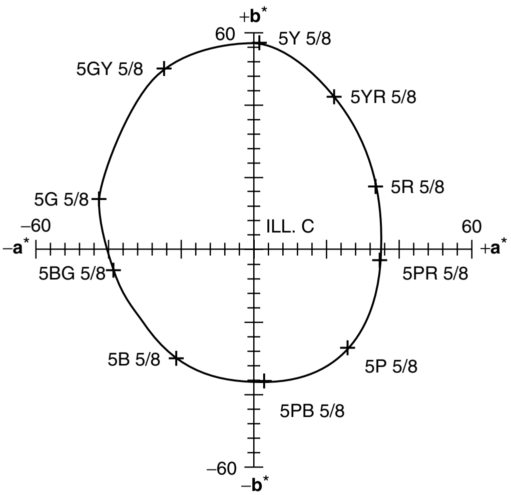

Fig. 12.11 The Munsell hue circle plotted in CIELAB color space.

the redness (positive values)-greenness (negative) axis a^*, and the yellowness (positive)-blueness (negative) axis b^* are calculated from Eqs (12.10)–(12.12):

$$L^* = 116f\left(\frac{Y}{Y_n}\right)^{1/3} - 16 \qquad (12.10)$$

$$a^* = 500\left[f\left(\frac{X}{X_n}\right)^{1/3} - f\left(\frac{Y}{Y_n}\right)^{1/3}\right] \qquad (12.11)$$

$$b^* = 200\left[f\left(\frac{Y}{Y_n}\right)^{1/3} - f\left(\frac{Z}{Z_n}\right)^{1/3}\right] \qquad (12.12)$$

When X/X_n, Y/Y_n, $Z/Z_n \geq 0.008856$, then $f(X/X_n) = (X/X_n)^{1/3}$, $f(Y/Y_n) = (Y/Y_n)^{1/3}$ and $f(Z/Z_n) = (Z/Z_n)^{1/3}$, where X_n, Y_n, and Z_n, are the tristimulus values of the illuminant or white point.

When X/X_n, Y/Y_n, $Z/Z_n < 0.008856$, then $f(X/X_n) = 7.787(X/X_n) + 16/116$, $f(Y/Y_n) = 7.787(Y/Y_n) + 16/116$, and $f(Z/Z_n) = 7.787(Z/Z_n) + 16/116$.

For workers who prefer working with lightness, chroma, and hue coordinates, the CIE defined chroma and hue angle as shown in Eqs (12.13) and (12.14). Note that the hue angle is measured in degrees.

$$C^* = \left(a^{*2} + b^{*2}\right)^{1/2} \qquad (12.13)$$

$$h = \tan^{-1}\left(\frac{b^*}{a^*}\right) \qquad (12.14)$$

These correlate well with visual judgments of lightness, chroma, and hue, respectively.

Figure 12.11 illustrates the Munsell hue circle plotted in CIELAB color space. CIELAB is much closer to a visually uniform color space than the 1931 or 1964 color spaces.

A chromaticity diagram was not defined for the CIELAB color space.

12.4.3
The 1976 CIE $L^*u^*v^*$ (CIELUV) Color Space

Since some industries, such as television and video displays, find chromaticity diagrams useful, the CIE also recommended the CIELUV color space that does have a chromaticity diagram. Values for the CIELUV coordinates are calculated from Eqs (12.15)–(12.22):

$$L^* = 116\left(\frac{Y}{Y_n}\right)^{1/3} - 16 \text{ when } \frac{Y}{Y_n} > 0.008856 \quad (12.15)$$

$$L^* = 903.3\left(\frac{Y}{Y_n}\right)^{1/3} \text{ when } \frac{Y}{Y_n} \leq 0.008856 \quad (12.16)$$

$$u^* = 13L^*(u' - u'_n) \quad (12.17)$$

$$v^* = 13L^*(v' - v'_n) \quad (12.18)$$

where the chromaticity coordinates of the color (u', v') are defined as

$$u' = \frac{4X}{X + 15Y + 3Z} \quad (12.19)$$

$$v' = \frac{9X}{X + 15Y + 3Z} \quad (12.20)$$

and the chromaticity coordinates of the illuminant or white point are defined as

$$u'_n = \frac{4X_n}{X_n + 15Y_n + 3Z_n} \quad (12.21)$$

$$v'_n = \frac{9X_n}{X_n + 15Y_n + 3Z_n} \quad (12.22)$$

The CIE also defined chroma, C^*_{uv}, and hue angle, h_{uv}, coordinates for CIELUV that are calculated using Eqs (12.23) and (12.24):

$$C^*_{uv} = \left(u^{*2} + v^{*2}\right)^{1/2} \quad (12.23)$$

$$h_{uv} = \arctan\left(\frac{v^*}{u^*}\right) \quad (12.24)$$

In addition, the CIE defined a correlate to perceived saturation, S^*_{uv}, that is calculated using either Eq. (12.25) or its equivalent Eq. (12.26):

$$S^*_{uv} = \frac{C^*_{uv}}{L^*} \quad (12.25)$$

$$S^*_{uv} = 13\left[\left(u' - u'_n\right)^2 + \left(v' - v'_n\right)^2\right]^{1/2} \quad (12.26)$$

The perceived saturation, S^*_{uv}, remains constant for a series of colors of constant chromaticity as the lightness increases or decreases (Hunt, 1991).

12.5
Color Differences and Tolerances

Most of the time, industrial color matching and production involve the evaluation and description of color differences. A colorist may be evaluating two lots of different pigments or dyes, comparing a target color with a laboratory sample or comparing a product standard with a production batch. Qualitatively describing the color differences is essential and being able to quantify the color difference is extremely useful. People are most sensitive to differences in hue, more sensitive to differences in chroma, and least sensitive to differences in lightness. This is the result of how colors change in nature. For example, a shadow falling across a fence results in the fence being darker in the shadow area. Although this is an actual color difference based on the difference in lightness, a person attributes the difference to the shadow and not to the color of the fence itself.

Distinguishing between the perceptibility of two colors and the acceptability of a color match are extremely important. A color difference between two samples is perceptible if you can see the color difference between them. Although you may be able to perceive the color difference between a product standard and a production batch, the difference in color may still be acceptable to the user or consumer. A color tolerance tells the colorist to what extent a color difference is acceptable between the standard and the batch. The size of the color tolerance depends on the product and how it is being used. For example, the color difference between two bolts of dyed fabric must be very small if you intend to make a suit using both bolts. However, the tolerance may be much larger if the bolts would not be used together and will be viewed as separate products.

Colorists and designers have used many terms for describing color differences. They describe the differences between two colors as being stronger, duller, slightly blue, and too gray. Designers have asked colorists to make a color "happier." Unfortunately, most of those terms do not help the colorist decide how to adjust the batch since one person's "slightly" may be another person's "strongly." And how do you make a color "happier"? For chromatic colors, the author recommends using the terms lightness, chroma, and hue to describe color differences. The batch is either equal in lightness to the standard or darker or lighter. The batch may have the same, a higher, or a lower chroma than the standard. Hue differences are usually described in terms of redness, yellowness, greenness, or blueness. A red or green sample may be yellower or bluer than the standard, and a yellow or blue sample may be redder or greener than the standard. For example, a red sample may be moderately yellower, slightly darker, and lower in chroma than the standard. For neutral- and low-chroma colors, it is often useful to describe color differences in terms of lightness, redness-greenness, and yellowness-blueness. The visual color difference between a low-chroma color standard and a batch can often be larger and still acceptable if both are in the same red-green and yellow-blue quadrants of color space.

Although many people rely upon an instrumental evaluation of color difference, the color of the final product is often evaluated visually. Regardless of whether or not an instrumental color difference is within a specified tolerance, there will be problems if the color does not look right. Therefore, before instrumental measurements are made, color and gloss differences between a standard and a sample should be evaluated visually. Visual evaluations should be made in light booths using standardized viewing conditions (ASTM 4449; ASTM 1729; ASTM 3928; ASTM 2616). Small-to-moderate color differences can be quantitatively evaluated visually by using a gray scale (ASTM 2616). Visually prepared color-tolerance sets consist of samples having acceptable color differences at the extremes of lightness–darkness, high- and low-chroma and the redness-greenness or yellowness-blueness differences in hue. A visual color-tolerance set can be measured to provide a set of instrumental color tolerances.

To obtain the most accurate instrumental evaluation of color difference, the standard and the batch should have the same texture and gloss. Some instruments will make measurements that minimize the affect of texture and gloss differences while others will accentuate the differences. The human eye–brain evaluation of color difference has a perceptibility tolerance as does instrumental measurements. An instrumental measurement, and the resulting color-difference calculation, may produce differences that are below those perceptible to a person. Care must be taken not to set an instrumental tolerance below which a person can perceive.

Some research has taken place on the optimum methods for calculating color differences. This has led to a number of published color-difference equations. Some of the equations correlate better with human perception than others. The goal of a color-difference equation is generally to determine a single number that will determine whether a batch is acceptable to a standard. Even though most industrial colorists tend to use a single-number color-difference tolerance, better results are usually obtained when tolerances are set for each component of the color difference.

12.5.1
Single-Number Color Scales

In some cases, the color of a sample varies along a single direction in color space, which can be adequately described by a single scale value. This occurs in the evaluation of whiteness and yellowness and in the evaluation of some liquids.

12.5.1.1 Whiteness Scales

Whiteness scales indicate the deviation from an ideal white, which is typically assigned a whiteness value of 100. Equation (12.27) represents a commonly used whiteness scale equation (ASTM 313):

$$WI = Y + (WI, x)(x_n - x) + (WI, y)(y_n - y) \qquad (12.27)$$

where Y, x, and y are the luminance factor and the chromaticity coordinates of the batch; x_n and y_n are the chromaticity coordinates for the CIE standard illuminant and source used; and WI, x and WI, y are numerical coefficients that are specified in Table 12.1. The whiteness index is valid only for specimens with $40 < WI < (5Y - 280)$.

A tint index often accompanies a whiteness index to indicate the direction in which the white varies. Equation (12.28) represents the tint index for the whiteness scale in Eq. (12.27):

$$T = (T, x)(x_n - x) + (T, y)(y_n - y) \qquad (12.28)$$

where x and y are the chromaticity coordinates of the batch; x_n and y_n are the chromaticity coordinates for the CIE standard illuminant and source used;

Tab. 12.2 Coefficients of the equation for yellowness index.

Value	CIE Standard Illuminant and observer			
	C, 1931	D_{65}, 1931	C, 1964	D_{64}, 1964
C_X	1.2769	1.2985	1.2871	1.3013
C_Z	1.0592	1.1335	1.0781	1.1498

and T, x and T, y are numerical coefficients that are specified in Table 12.1. The tint index is valid only for specimens with $-3 < T < +3$.

12.5.1.1 **Yellowness Indices**

Yellowness indices are often used to describe the yellowing of clear plastics and white paints. They show the departure of a batch from neutral toward yellow. Equation (12.29) represents a commonly used yellowness index equation (ASTM 313):

$$YI = \frac{100\,(C_X X - C_Z Z)}{Y} \qquad (12.29)$$

where X, Y, and Z are the tristimulus values of the batch and C_X and C_Z are numerical coefficients that are specified in Table 12.2.

12.5.1.2 **Scales for Liquids**

When only a limited range of color is involved, such as in the testing of the color of lacquer used in the paint industry, a simple comparison of the color of the batch with standard colored solutions or glasses ranging from colorless to highly colored can be made. A standardized series of these solutions or glasses is used to provide a specialized color scale. The color is often a measure of concentration of ingredient. One difficulty in using these special color scales is that the color of the specimen may not match with that of the standard; this can make rating on a single-number scale difficult. Nevertheless, their simplicity, low cost, and adaptability to special situations have resulted in wide use of single-number scales for certain applications (ASTM 156; ASTM 1209; ASTM 1500; ASTM 6045; ASTM 1544; ASTM 6166; ASTM 1686).

12.5.2
The CIELAB and CIELUV Color-Difference Equations

In addition to recommending the CIELAB and CIELUV color spaces, in 1976 the CIE also recommended color-difference equations for those spaces (CIE, 2004).

12.5.2.1 **The CIELAB Color-Difference Equation**

The popularity of this color space increased through the 1980s and became the most commonly used color space in industry. To calculate CIELAB color difference, the L^*, a^*, and b^* values of the batch or sample color are subtracted from those of the standard or target color (ASTM 2244):

$$\Delta L^* = L^*_{\mathrm{batch}} - L^*_{\mathrm{standard}} \qquad (12.30)$$

$$\Delta a^* = a^*_{\mathrm{batch}} - a^*_{\mathrm{standard}} \qquad (12.31)$$

$$\Delta b^* = b^*_{\mathrm{batch}} - b^*_{\mathrm{standard}} \qquad (12.32)$$

A negative value of ΔL^* indicates that the batch is darker than the standard, whereas a positive value indicates that the batch is lighter than the standard. A negative value of Δa^* indicates that the batch is greener than the standard, whereas a positive value of Δa^* indicates that the batch is redder than the standard. A negative value of Δb^* indicates that the batch is bluer than the standard, whereas a positive value indicates that the batch is yellower than the standard.

The total color difference between the batch and standard is given by Eq. (12.33):

$$\Delta E^*_{ab} = \left[\left(\Delta L^*\right)^2 + \left(\Delta a^*\right)^2 + \left(\Delta b^*\right)^2\right]^{1/2} \tag{12.33}$$

The chroma difference between the batch and standard is given by

$$\Delta C^*_{ab} = C^*_{\text{batch}} - C^*_{\text{standard}} \tag{12.34}$$

The hue difference is not the difference in the hue angle. It is that part of the color difference that is left after accounting for the lightness and chroma differences. The hue difference between the batch and standard, $\Delta H^*{}_{ab}$, is calculated using Eq. (12.35):

$$\Delta H^*_{ab} = \left[\left(\Delta E^*_{ab}\right)^2 + \left(\Delta L^*\right)^2 + \left(\Delta C^*_{ab}\right)^2\right]^{1/2} \tag{12.35}$$

The sign of $\Delta H^*{}_{ab}$ is taken as positive if the hue angle of the batch is greater than that of the standard and is taken as negative if the hue angle is less than that of the standard.

The notations DL^*, Da^*, Db^*, DC^*, DH^*, and DE^* are often substituted for ΔL^*, Δa^*, Δb^*, ΔC^*_{ab}, ΔH^*_{ab}, and ΔE^*_{ab}.

12.5.2.2 **The CIELUV Color-Difference Equation**

Calculating the CIELUV color differences is very similar to calculating the CIELAB color differences (ASTM 2244):

$$\Delta L^* = L^*{}_{\text{batch}} - L^*{}_{\text{standard}} \tag{12.36}$$

$$\Delta u^* = u^*{}_{\text{batch}} - u^*{}_{\text{standard}} \tag{12.37}$$

$$\Delta v^* = v^*{}_{\text{batch}} - v^*{}_{\text{standard}} \tag{12.38}$$

A negative value of ΔL^* indicates that the batch is darker than the standard, whereas a positive value indicates that the batch is lighter than the standard. Δu^* *and* Δv^* represent differences in the chromaticity coordinates but are not associated with color names as are Δa^* and Δb^*.

The total color difference between the batch and standard is given by Eq. (12.39):

$$\Delta E^*_{ab} = \left[\left(\Delta L^*\right)^2 + \left(\Delta u^*\right)^2 + \left(\Delta v^*\right)^2\right]^{1/2} \tag{12.39}$$

The chroma difference between the batch and standard is given by

$$\Delta C^*_{uv} = C^*_{uv,\text{batch}} - C^*_{uv,\text{standard}} \tag{12.40}$$

The hue difference is not the difference in the hue angle. It is that part of the color difference that is left after accounting for the lightness and chroma differences. The hue difference between the batch and the standard, ΔH^*_{uv}, is calculated using Eq. (12.41):

$$\Delta H^*_{uv} = \left[\left(\Delta E^*_{uv}\right)^2 + \left(\Delta L^*\right)^2 + \left(\Delta C^*_{uv}\right)^2\right]^{1/2} \tag{12.41}$$

The sign of $\Delta H^*{}_{uv}$ is taken as positive if the hue angle of the sample is greater than that of the standard and is taken as negative if the hue angle is less than that of the standard.

The notations DL^*, Da^*, Db^*, DC^*, DH^*, and DE^* are often substituted for ΔL^*, Δa^*, Δb^*, ΔC^*_{uv}, ΔH^*_{uv}, and ΔE^*_{uv}.

12.5.3
The CMC(*l* : *c*) Color-Tolerance Equation

A number of new color-difference and color-tolerance equations have been developed since the adoption of the CIELAB equations. One of these, known as the *CMC*($l:c$) *equation* (CIE, 2004; ASTM 2244; McDonald, 1980; AATCC, 173–1992), is a modification of CIELAB that has improved uniformity of visual perception of its color differences. The CMC($l:c$) equation has found widespread use in the industry and is now more popular than CIELAB. The CMC($l:c$) equation is more appropriately called a *color-tolerance equation* rather than a color-difference equation. A color-difference equation calculates the same numeric value regardless of which specimen is used – the batch or the standard. A color-tolerance equation will calculate different values depending upon the position of the standard in color space. The CMC($l:c$) equation modifies the ΔL^*, ΔC^*, and ΔH^* components of the CIELAB color difference before calculating the total color difference:

$$\Delta E_{\text{CMC}}\left(l:c\right) = cf* \sqrt{\left(\frac{\Delta L^*}{l*S_L}\right)^2 + \left(\frac{\Delta C^*}{c*S_C}\right)^2 + \left(\frac{\Delta H^*}{S_H}\right)^2} \tag{12.42}$$

$$S_L = \frac{0.040975*L^*}{1+(0.01765*L^*)} \quad \text{for } L^* \geq 16 \tag{12.43}$$

$$S_L = 0.511 \quad \text{for L}^* < 16 \tag{12.44}$$

$$S_C = \frac{0.0638*C^*}{1+(0.0131*C^*)} + 0.638 \tag{12.45}$$

$$S_H = S_C*((F*T)+1-F) \tag{12.46}$$

in which

$$F = \left\{\frac{(C)^4}{(C)^4+1900}\right\}^{1/2} \tag{12.47}$$

$$T = 0.56 + \text{abs}\left|0.2*\cos\left(h+168^\circ\right)\right| \quad \text{if } 164^\circ < h < 345^\circ \tag{12.48}$$

or

$$T = 0.36 + \text{abs}\left|0.4*\cos\left(h+35^\circ\right)\right| \quad \text{for other values of } h \tag{12.49}$$

where "abs" indicates the absolute, that is, positive value of the term inside the brackets.

The parameters l and c weight the relative contributions of lightness to chromaticity in the color difference and compensate for systematic bias or parametric effects such as texture and sample separation. The most common values for $l:c$ are 2 : 1. The parameter *cf* is a commercial factor (AATCC 173–1992) used to adjust the total volume of the tolerance region so that accept/reject decisions can be made on the basis of a unit value of the tolerance.

12.5.4
The CIEDE 2000 Color-Difference Equation

Research was continued to find a better color-difference equation than CMC ($l:c$). The CIE developed an equation that correlates better with human perception than the CMC($l:c$) equation. This equation was recommended by the CIE in 2001 and is called *CIEDE2000* (CIE, 2001). Equations (12.50)–(12.66) are required to calculate CIEDE2000 (ASTM 2244):

$$L' = L^* \tag{12.50}$$

$$a^* = (1 + G)^* a^* \tag{12.51}$$

$$b' = b^* \tag{12.52}$$

$$C' = \sqrt{(a')^2 + (b')^2} \tag{12.53}$$

$$h' = \arctan\left(\frac{b'}{a'}\right) \tag{12.54}$$

$$G = 0.5 * \left(1 - \sqrt{\frac{(\overline{C}^*)^7}{(\overline{C}^*)^7 + 25^7}}\right) \tag{12.55}$$

where $\overline{C}^*$ is the arithmetic mean of the CIELAB C* values for the pair of specimens (standard and batch).

$$\Delta L' = L'_B - L'_S \tag{12.56}$$

$$\Delta C' = C'_B - C'_S \tag{12.57}$$

$$\Delta H = \frac{(a'_S * b'_B) - (a'_B * b'_S)}{\sqrt{0.5 * [(C'_S * C'_B) + (a'_S * a'_B) + (b'_S * b'_B)]}} \tag{12.58}$$

$$\Delta E_{00}(K_L, K_C, K_H) = \sqrt{\left(\frac{\Delta L^*}{K_L * S_L}\right)^2 + \left(\frac{\Delta C^*}{K_C * S_C}\right)^2 + \left(\frac{\Delta H^*}{K_H * S_H}\right)^2 + R_T * \left(\frac{\Delta C' * \Delta H'}{K_C * S_C * K_L * S_H}\right)} \tag{12.59}$$

The factors K_L, K_C, and K_H are correction terms for variation in perceived color-difference due to the viewing conditions. To obtain color-differences similar to CMC(2 : 1), set $K_L = 2$ and $K_C = K_H = 1$:

$$S_L = 1 + \frac{0.015 * \left(\overline{L}' - 50\right)^2}{\sqrt{20 + \left(\overline{L}' - 50\right)^2}} \tag{12.60}$$

where $\overline{L}'$ is the arithmetic mean of the CIELAB L' values for the pair of specimens (standard and batch).

$$S_C = 1 + \left(0.045 * \overline{C}'\right) \tag{12.61}$$

where $\overline{C}'$ is the arithmetic mean of the CIELAB C' values for the pair of specimens (standard and batch).

$$S_H = 1 + \left(0.015 * \overline{C} * T\right) \tag{12.62}$$

$$\begin{aligned} T = 1 &- \left[0.17 * \cos\left(\overline{h}' - 30^\circ\right)\right] \\ &+ \left[0.24 * \cos\left(2\overline{h}'\right)\right] \\ &+ \left[0.32 * \cos\left(3\overline{h}' + 6^\circ\right)\right] \\ &- \left[0.20 * \cos\left(4\overline{h}' - 63^\circ\right)\right] \end{aligned} \tag{12.63}$$

where $\overline{h}'$ is the arithmetic mean of the CIELAB L' values for the pair of specimens (standard and batch). All angles are in degrees. Care should be taken while calculating the mean hue angle if the color-difference pair has samples in different quadrants. For example, a color-difference pair has hue angles of 30° and 300°. The mean hue angle for this example is 345°. To determine the mean correctly, calculate the absolute difference of the hue angles. If the absolute difference is larger than

180°, then add 360° to the smaller hue angle and divide that sum by 2:

$$R_T = -R_C * \sin(2 * \Delta\theta) \qquad (12.64)$$

$$R_C = 2 * \sqrt{\frac{\left(\overline{C}'\right)^7}{\left(\overline{C}'\right)^7 + 25^7}} \qquad (12.65)$$

$$\Delta\theta = 30 * \exp\left\{-\left[\frac{\overline{h}' - 275^\circ}{25}\right]^2\right\} \qquad (12.66)$$

Although the CIEDE2000 equation correlates better with the existing data sets, it is not as popular as the CMC($l : c$) equation.

12.5.5
The DIN 99 Color-Tolerance Equation

The concept behind the CMC($l : c$) and CIEDE2000 equations involved changing the color-difference components of the CIELAB color-difference equation to make the final equation agree more closely with human perception. A committee of the Deutsches Institut für Normung e.V. (DIN) in Berlin, Germany, took a different approach for developing an improved color-difference equation. The idea behind DIN99 is to retain a Euclidean color-difference formula by correcting the nonuniformity of CIELAB color space (DIN 6176). Equations (12.67)–(12.78) define the new color space and the steps for the calculation of a DIN99 color difference:

Red-green axis:

$$e = a^* \cos(16^\circ) + b^* \sin(16^\circ) \qquad (12.67)$$

Yellow-blue axis:

$$f = 0.7\left(-a^* \ \sin(16^\circ) + b^* \ \cos(16^\circ)\right) \qquad (12.68)$$

Chroma:

$$G = \sqrt{e^2 + f^2} \qquad (12.69)$$

Hue angle:

$$h_{ef} = \arctan\left(\frac{f}{e}\right) \qquad (12.70)$$

which are used to develop a new coordinate system defined as

$$L_{99} = 105.51 \frac{\ln(1 + 0.0158\ L^*)}{k_e} \qquad (12.71)$$

$$a_{99} = C_{99}\ \cos(h_{99}) \qquad (12.72)$$

$$b_{99} = C_{99}\ \sin(h_{99}) \qquad (12.73)$$

where

$$C_{99} = \frac{\ln(1 + 0.045\ G)}{0.045 k_{CH} k_e} \qquad (12.74)$$

$$h_{99} = h_{ef} \frac{180}{\pi} \qquad (12.75)$$

and k_{CH} and k_e are adjustable parameters. The color difference is given by the Euclidean distance:

$$\Delta E_{99} = \sqrt{(\Delta L_{99})^2 + (\Delta a_{99})^2 + (\Delta b_{99})^2} \qquad (12.76)$$

or

$$\Delta E_{99} = \sqrt{(\Delta L_{99})^2 + (\Delta C_{99})^2 + (\Delta H_{99})^2} \qquad (12.77)$$

where ΔH_{99} is defined as

$$\Delta H_{99} = \sqrt{(\Delta a_{99})^2 + (\Delta b_{99})^2 - (C_{99})^2} \qquad (12.78)$$

which is similar to the corresponding CIELAB definition.

It remains to be seen which approach to the color-difference problem will gain acceptance. The CIE continues to have groups working on the problem of a more uniform color space as well as improved color-difference equations.

12.5.6
Setting Instrumental Color Tolerances

As with all measurements, instrumental color measurement has variation. The sources of the variation include not only the instrument itself but also variation in the sample itself. Some samples are more homogeneous than others and some instruments have less variation than others. In addition, all manufacturing processes cause variation in color. A colorist must consider the variation of the whole manufacturing and measurement system when setting instrumental color tolerances. Unfortunately, there is a tendency among a number of colorists to expect the total color difference to be zero. Making multiple measurements on real samples demonstrate that this is not possible. Setting a tolerance below the perceptibility limit is a waste of time because the customers will not see that color difference. The closer the tolerance is to the perceptibility limit, the more expensive it is to produce the product. A compromise must be made in determining the limits of an acceptable, instrumental color-difference tolerance.

The first step in determining an instrumental tolerance is to know the variation in the manufacturing and measurement processes. Measuring multiple samples of multiple batches can provide this information. Unless the seller wants to select, or blend, batches of product, the tolerances cannot be set to limits less than those found in this step. Preliminary tolerances are usually set based on past experience where it is not practical, or too expensive, to determine actual production limits initially for a new color. Final tolerances are determined after the seller gets some experience with making the color. Measuring a number of batches that the customer has judged relative to the standard helps to more accurately determine the acceptability limits (ASTM 3134).

Another method of setting instrumental tolerances is from measurements of a visually prepared color-tolerance set. Designers and marketing personnel usually determine these color-difference limits of these sets before the color is actually manufactured. It is possible that the color-tolerance set might be tighter than the manufacturing variations. The colorist preparing the color-tolerance set must caution the buyer not to set the tolerances so tight that the product cannot be produced within the tolerances.

12.6
Instrumental Color Measurement

12.6.1
Measuring Reflectance

12.6.1.1 Specular and Diffuse Reflectance

If we shine a beam of light onto a perfect mirror from the left at 45° from its normal, the light will be reflected to the right at 45° from the normal. The light does not penetrate the surface of the mirror. The mirrorlike reflection from the surface of a sample is called *specular reflection.*

If we shine a beam of light onto a very good diffuser, such as a compressed pellet of barium sulfate, the light will enter the material and get scattered (redirected) many times by the barium sulfate particles. Eventually the light will find its way out of the interior of the pellet and the barium sulfate tablet will appear to reflect light in all directions as shown in Figure 12.12.

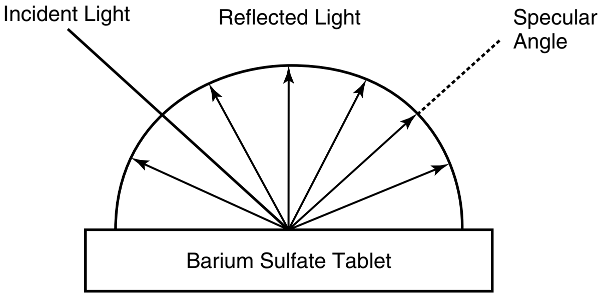

Fig. 12.12 Diffuse light reflected from a barium sulfate tablet.

Most materials have some specular reflection and some diffuse reflection as shown in Figure 12.13. Materials with very high gloss will have very narrow cones at the specular angle. As the gloss decreases, the specular cone widens. About 4% of the light reflected from glossy paint samples and glossy plastic samples will be specular reflection. The remaining 96% will be diffusely reflected.

12.6.1.2 **Illuminating and Viewing Geometries**

Color-measuring instruments consist of an illuminator, a specimen holder, and a receiver. The illuminator contains the light source and associated optics necessary to illuminate the specimen. An illuminator may also contain a diffraction grating or filters, diffusers, and various electronics. The receiver contains the components and optics necessary to gather and analyze the light reflected from the specimen. A receiver may also contain a diffraction grating or filters, diffusers, and various electronics. These components may be arranged in a variety of ways depending upon what the optical designer wants to measure. The CIE has recommended four illuminating and viewing geometries for color measurement (CIE, 2004; CIE, 1995). Two of them are bidirectional and two of them are diffuse. A number of factors should be considered when deciding upon which illuminating and viewing geometry is best for a given type of color

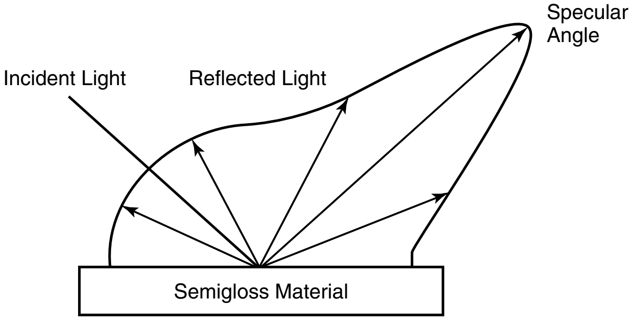

Fig. 12.13 Light reflected from a semigloss material with both a diffuse component and a specular component.

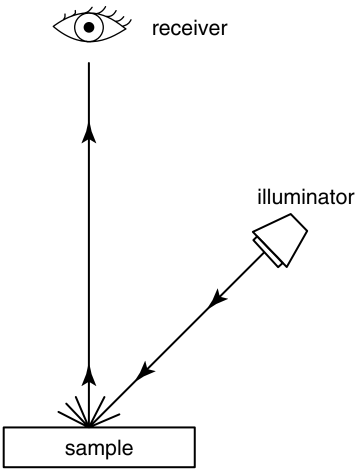

Fig. 12.14 The 45 : 0 illuminating and viewing geometry.

measurement (ASTM 179; Rich, 1988; Mabon, 1992).

Bidirectional geometries illuminate the specimen with a narrow beam of light and gather the reflected light with a receiver having a narrow field of view. One of the CIE bidirectional recommendations is to illuminate the specimen at 45° from its normal and view the reflected light along the specimen's normal. This illuminating and viewing geometry is called 45 : 0 and is shown in Figure 12.14. The CIE also recommends the reverse geometry (0 : 45) in which the specimen is illuminated along its normal and viewed at 45° from its normal. Both geometries produce equivalent results for nonfluorescent samples that do not contain metallic flakes or interference pigments (ASTM 179; Billmeyer and Marcus, 1969). The 45 : 0 and 0 : 45 geometries do not measure the specular reflection from a specimen and simulate the viewing conditions under which many specimens are evaluated visually. These measurements are sensitive to the texture of the specimen and any polarization affects that may occur when light enters the specimen. Multiple measurements should be made to average the differences due to the sample's texture. Using annular or circumferential illumination (or viewing) also minimizes texture and polarization affects. Circumferential illumination provides illumination (or the receiver will gather the reflected light) in many beams distributed at uniform intervals around the 45° cone about the sample's normal, *c* : 45 (or 45 : *c*). Annular illumination provides illumination (or the receiver will gather the reflected light) continuously and uniformly around the 45° cone about the specimen's normal, *a* : 45 (45 : *a*). Because of the surface texture influence, measurements made with bidirectional geometries are sometimes described as measuring appearance rather than color. Instruments with bidirectional geometries are very popular in the graphics arts community.

Figure 12.15 illustrates the most popular of the CIE diffuse geometries called *diffuse/normal* or *d* : 0. The illuminator shines light on the wall of an integrating sphere. An integrating sphere is a hollow metal sphere coated with an efficient white diffusing material. The most

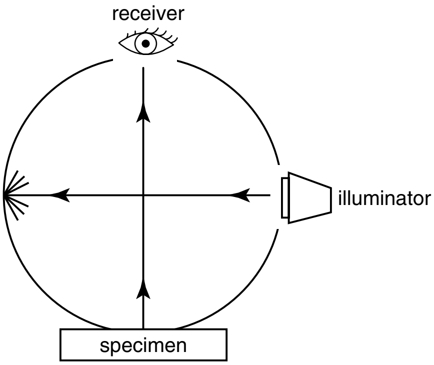

Fig. 12.15 The diffuse-normal (*d* : 0) illuminating and viewing geometry.

common integrating sphere coatings are barium sulfate ($BaSO_4$) and polytetrafluoroethylene (PTFE). Hollowing a block of PTFE has been used to create some spheres. Ports are cut into the wall of the integrating sphere, which are needed for the illuminator and the receiver. The light from the illuminator is scattered in all directions, which uniformly illuminates the integrating sphere that then acts as a diffuse hemispherical illuminator to illuminate the sample. The receiver views the specimen along its normal. Baffles are used to prevent light from the integrating sphere wall from entering the receiver directly. In the other CIE diffuse geometry (normal/diffuse or 0 : *d*), the specimen is illuminated directly along its normal and the diffuse light from the specimen uniformly illuminates the integrating sphere. The receiver then views the wall of the integrating sphere. Both geometries produce equivalent results.

Neither of the two recommended diffuse geometries measures the specular reflection from the sample. By making a slight modification to the diffuse geometries, the specular reflection from the sample can also be measured. The modification, shown in Figure 12.16, involves moving the receiver or illuminator slightly off the sample's normal (6–8°). When this modification is used, a third port (the specular port) is cut in the

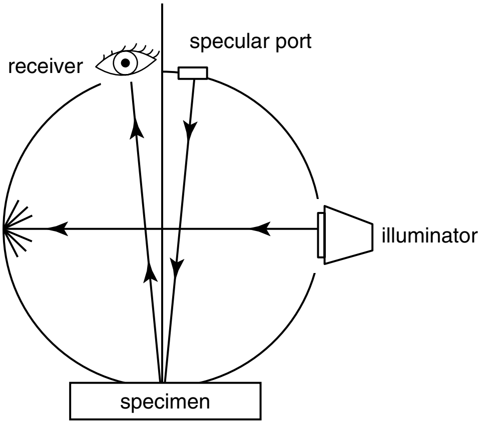

Fig. 12.16 The diffuse near-normal (*d* : 0 : *i*) illuminating and viewing geometry.

integrating sphere wall. To include the sample's specular reflection, a white cap is used to cover the specular port. The white cap should have the same reflectance as the wall of the integrating sphere. The two geometries including the specimen's specular reflection are called, respectively, *total/near-normal* ($d : 0 : i$) and *near-normal/total* ($0 : d : i$). To exclude the specimen's specular reflection, a light trap is used for the specular port. The two geometries excluding the specimen's specular reflection are called *diffuse/near-normal* ($d : 0 : e$) and *near-normal/diffuse* ($0 : d : e$). The gloss and texture of the specimen will have little effect on the color measurements when the specimen's specular reflection is included. Thus, many colorists prefer this geometry for computerized color matching. Measuring highly glossy specimens using one of the diffuse geometries with the specular reflection excluded will correlate with a bidirectional 45 : 0 instrument. This correlation will also occur for perfectly matte specimens for which there are not a noticeable specular reflection peak. Since the shape of the specular reflection varies by material and specimen and is poorly defined, designing the perfect universal light trap, without affecting the measurement of the diffuse reflectance, is impossible (Budde, 1980). The amount of the specular reflection trapped is also dependent upon the design of the instrument and of the integrating sphere.

12.6.1.3 **Spectrophotometers, Colorimeters, Spectrocolorimeters, and LED-Based Instruments**

Spectral reflectance values are required to calculate tristimulus values and color coordinates. Spectrophotometers measure the reflection (or transmission) characteristics of a specimen at different wavelengths of the visible spectrum. Spectrophotometers have been manufactured in all of the recommended illuminating and viewing geometries. Although some spectrophotometers can measure the reflectance continuously at all wavelengths of the spectrum, others (abridged spectrophotometers) can only measure selected wavelengths. Many commercial spectrophotometers measure the reflectance in 10 nm increments.

Reflectance is the ratio of the amount of light reflected by a specimen relative to the amount of light illuminating the specimen. Most spectrophotometers actually measure reflectance factor rather than reflectance. Reflectance factor is the ratio of the amount of light reflected by a specimen relative to the amount of light that would be reflected from a perfect reflecting diffuser under the same geometric and spectral conditions of measurement. Many colorists use the term reflectance when they mean reflectance factor. This distinction becomes very important when measuring fluorescent materials, materials with metallic flakes, and materials with interference pigments. Although the reflectance from a specimen can never be greater than 1.0 (100%), the reflectance factor may exceed 1.0 by a significant amount for some materials.

Colorimeters measure broad areas of the light reflected from a specimen using broad-band filters or some other spectral defining device. The amount of light reflected is converted directly into tristimulus values or color coordinates such as L^*, a^*, and b^*. Because colorimeters usually are customized for only one illuminant/observer combination, they cannot measure metamerism.

Colorimeters are generally not as accurate as spectrophotometers because of the difficulties in matching the light source and filters to the combination of CIE illuminant spectral power distributions and color-matching functions. Many of the current colorimeters are based on video camera technology. These instruments are coupled with advanced image technology to make color measurements on small areas of a complex scene. This technology is particularly useful for materials whose appearance is naturally or intentionally nonuniform such as woven and patterned fabrics. Video-based instruments may also be used for online applications such as controlling color on web printing application.

Spectrocolorimeters are spectrophotometers that output only tristimulus values or color coordinates.

Several instruments that illuminate a specimen with light emitting diodes (LEDs) have been developed. Spectral reflectance factors, tristimulus values, and color coordinates are calculated from the reflected light.

12.6.1.4 **Standardization**

The first step in making accurate color measurements is to standardize the instrument. This means the zero point of the instrument and the high end of the photometric scale must be set. A light trap is often used to set the zero point of the instrument. Most instrument manufacturers provide a white ceramic tile for setting the high end of the photometric scale. The values of the white are traceable to a national standardizing laboratory such as the US National Institute for Standards and Technology (NIST). A number of other materials have been used to set the high end of the photometric scale. They include optical grade barium sulfate (BsSO4), optical grade PTFE, and opal glasses (ASTM 259; Carter, Billmeyer and Rich, 2000). Instruments should be standardized at regular intervals. In most industrial settings, they are standardized once per 8-hour shift.

12.6.1.5 **Repeatability, Reproducibility, and Accuracy**

Top-of-the-line color measuring instruments claim a short-term repeatability of 0.01 CIELAB units. This is based upon multiple measurements of a white standard. The interinstrument agreement (reproducibility) is claimed to be 0.15 CIELAB units (maximum), with an average of 0.08 CIELAB units. This claim is based upon reading a set of 12 colored tiles. It should be noted that the very low repeatability and reproducibility numbers could only be achieved with stable standards at a tightly controlled temperature. Accuracy is determined by comparing instrumentally measured results with those of a known standard. There are no known standards available for color measurement with ‘‘absolute’’ values. Fortunately most industrial color measurement is concerned with the comparative measurement of a standard (or target) to a batch (or trial). As long as the instruments are using the same illuminating and viewing conditions and have comparable repeatability and reproducibility, these measurements are adequate. Long-term instrument stability should be monitored as part of a good quality assurance program. A set of stable ceramic standards was designed for this purpose (Clark, 1971), but any set of stable standards can be used. Some instrument manufacturers and private laboratories have programs to help the colorist monitor his/her instruments.

The repeatability and reproducibility claimed by instrument manufacturers are tested under tightly controlled conditions with highly uniform samples. It is extremely unlikely that a colorist would be able to duplicate these claims in the field. More variation in a color measurement comes from the sample rather than from the instrument. Careful sampling and sample preparation can help reduce the variability. The colorists should determine the repeatability and reproducibility using their own materials under their typical measurement conditions. Knowing how the instrument performs under field conditions helps determine practical color tolerances. The variability in measuring real specimens in the field can be reduced by making multiple measurements (ASTM 1345).

12.6.1.6 Measuring Fluorescent Materials

Fluorescent materials do more than just reflect light. They absorb radiation at some wavelengths and emit light at wavelengths longer than those that were absorbed. This is in addition to the light reflected in the same region of the spectrum. For example, many white papers will absorb ultraviolet radiation (below 400 nm) and emit blue light. The higher energy in the blue region of the spectrum makes the paper appear whiter than paper that does not fluoresce.

If an instrument with monochromatic light illuminates a fluorescent specimen, and a receiver sensitive to the entire visible spectrum is used to measure the reflectance, the receiver will not be able to distinguish the amount of light reflected at that wavelength from the light emitted at the longer wavelength so that the reflectance will appear abnormally high. Monochromatic light illuminating the sample at the wavelength where light is emitted will result in the measurement of the true reflectance at that wavelength. Spectrofluorimeters that both illuminate the sample with monochromatic light and view the sample at a single (narrow band) of wavelengths for the complete measurement of fluorescent samples were developed.

Most industrial fluorescent materials are measured with instruments that illuminate the sample with a broadband polychromatic illuminator simulating CIE Illuminant D65. Some of these instruments have special filters to control the amount of ultraviolet illumination from the source to better simulate D65 as the lamp in the illuminator ages. These instruments measure the combined reflectance and emittance, which is the total spectral reflectance factor. Because of the emittance, the total spectral reflectance factor can be greater than 1.0.

To properly measure fluorescent samples, only the 45 : 0 or 0 : 45 illuminating/viewing geometry should be used (ASTM 991). Emitted fluorescent light in an integrating sphere lowers the efficiency of the integrating sphere, resulting in lower total spectral reflectance factors than when using the other geometries (McKinnon, 1987).

Gundlach and Terstiege (1994) recommended using fluorescent calibration standards to standardize single polychromator instruments to ensure the proper measurement of fluorescent specimens.

12.6.1.7 Measuring Materials Containing Metallic Flakes and Interference Pigments

Metallic flakes and interference pigments are called *effect pigments*. When a

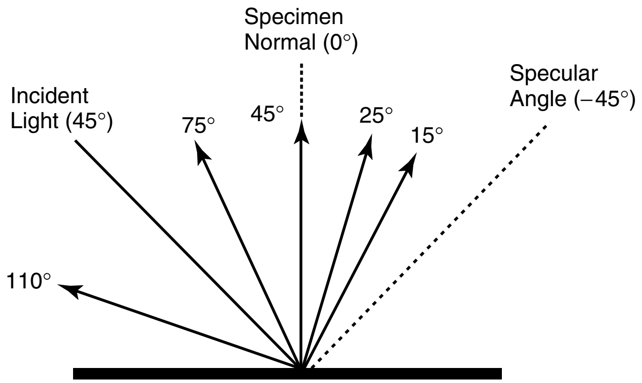

Fig. 12.17 The illuminating and viewing geometries used for the measurement of metal flake pigmented materials. The ASTM recommends using the aspecular angles of 15, 45, and 110°.

material is colored with these pigments, one or more of the attributes of color change as the illumination or viewing angle is changed. This is called *gonioapparance.*

Materials colored with only metallic flakes appear lighter when viewed near the specular angle than when viewed at angles farther away from the specular angle. This change in lightness is called *flop* in the coatings industry. The larger the metallic flakes, the greater the flop. Metallic flakes also add a sparkling appearance to the material. Multiangle instruments (sometimes called *goniospectrophotometers*) were designed to measure materials containing metallic flakes. These instruments are modifications of the common 45 : 0 bidirectional instruments. The ASTM specifies the angles of illumination and viewing by the illumination anormal angle, the viewing (detection) anormal angle, and the viewing aspecular angle enclosed in parenthesis (ASTM 2175). An anormal angle is an angle measured from the specimen normal in the illuminator plane unless otherwise specified. Positive anormal angles are usually diagrammed to the left of the specimen normal on the same side as the illuminator. An aspecular angle is a viewing angle measured from the specular direction in the illuminator plane unless otherwise specified (ASTM E284). Positive aspecular angles are in the direction toward the illuminator axis. Research instruments let the colorist specify the angles of illumination and view. Portable instruments illuminate the sample at 45° from the normal. Portable instruments view the specimen at three to five aspecular angles (see Figure 12.17). Most five-angle instruments would view the specimen at aspecular angles of 15, 25, 45, 75, and 110°. A three-angle instrument would use either 15° (preferred) or 25, 45° and either 75 or 110° (preferred) (ASTM 2194). The aspecular angle of 45° corresponds to an illuminating/viewing geometry of 45 : 0 or 45° : 0° (as 45) using the ASTM notation.

Measuring materials colored with interference pigments is a more difficult problem. The color of an interference

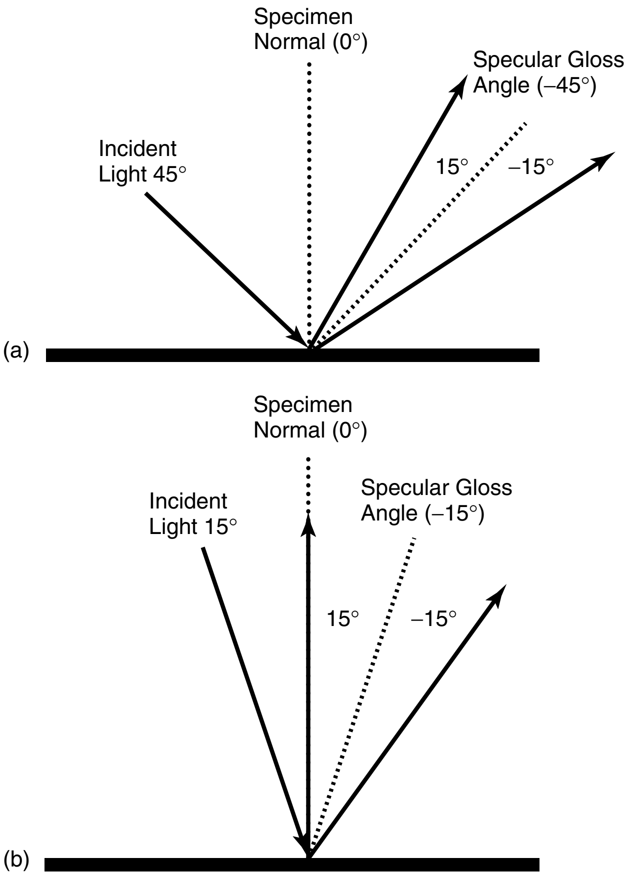

Fig. 12.18 The ASTM recommended viewing geometries used for the multiangle color measurement of interference pigments. (a) The specimen is illuminated by incident light at an anormal angle of 45°. (b) The specimen is illuminated by incident light at an anormal angle of 15°. The specimen normals and specular gloss angles are shown as anormal angles. The two viewing angles for each illumination angle are shown as aspecular angles.

pigment is seen only near the angle of the specular reflection. As the angle of the illuminator changes, the angle of specular reflection changes. The hue and chroma of the interference pigment change as the specular angle changes. Thus, an observer can see extreme changes in hue as the specular angle changes. To measure this effect, you need more than one angle of illumination in addition to multiple angles of view (see Figure 12.18a and b). The ASTM specifies that the minimum requirement for an instrument measuring interference pigments is to have two illuminators, one at an anormal angle of 45° and one at an anormal angle of 15°. Two aspecular viewing angles (−15 and +15°) are required for each illumination angle for a total of four angles (ASTM 2539). Some commercial

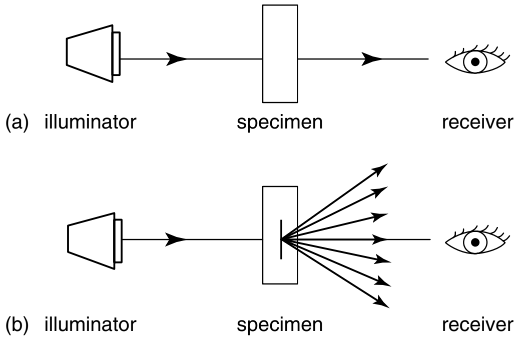

Fig. 12.19 The 0 : 0 illuminating and viewing geometry for measuring transmittance. This is only accurate for samples with no scattering (a). Hazy samples (b) cannot be measured using this illuminating and viewing geometry.

multiangle instruments have a third illuminator at an anormal angle of 65°.

Significant visual effects can be obtained by coloring a material using both metallic flakes and interference pigments. These specimens can be measured with multiangle instruments with multiple angles of illumination and multiple angles of view.

12.6.2
Measuring Transmittance

12.6.2.1 Regular and Diffuse Transmittance

Regular transmittance occurs in materials that can only absorb light. They may appear crystal clear or colored but totally transparent. Hazy materials not only absorb light but also scatter it as it passes through. They will appear to be almost, but not totally, transparent and may be clear or colored. Translucent materials reflect, transmit, and scatter light as it passes through. They will appear to be milky and may be white or colored.

12.6.2.2 Illuminating and Viewing Geometries

Although the CIE has recommended four geometries for transmittance, only three of them are commonly used for color measurement.

Spectrophotometers used for analytical chemistry measure transmittance using 0 : 0 illuminating/viewing geometry as shown in Figure 12.19(a) and (b). The illuminator illuminates the specimen along its normal and the receiver views the sample on the other side along it normal. This geometry measures transmittance accurately only for specimens that have regular transmission.

The diffuse-normal (*d* : 0) shown in Figure 12.15 and its reverse geometry normal-diffuse (0 : *d*) can be used to measure materials that transmit regularly or diffusely. To measure regular transmission, the specimen is placed away from the instrument's integrating sphere. To measure diffuse transmission, the specimen is placed in contact with the instrument's integrating sphere. When integrating sphere instruments designed for measuring reflectance are used, a white material with reflectance as close to that of the integrating sphere's wall is placed in the sample port.

12.6.2.3 Standardization

The instrument's zero point is usually set by blocking the light beam with an opaque material.

There are several ways of setting the high end of the photometric scale. The easiest technique is to make a measurement with nothing in the sample holder and set the transmittance factor to 1.0 at each wavelength. Transmittance measurements will then be relative to air. A totally colorless blank can be measured and the transmittance factor is set to 1.0 at each wavelength. It is important that this blank specimen be made of the same material and has the same thickness as the specimen to be measured. Transmittance measurements will then be relative to the clear specimen.

Liquid samples must be put into a sample holder before they are measured. An empty holder can be measured and the transmittance factor is set to 1.0 at each wavelength. Although the measurements would still be relative to air, the affect on transmission of the sample holder will be eliminated. Lastly, the liquid sample holder can be filled with water or a solvent of similar optical properties as that of the specimen. The transmittance measurements will then be relative to water or the solvent.

12.6.2.4 Measuring Transmittance

Specimens being measured should be flat with parallel sides. Curved specimens, such as lenses, are very difficult to measure because the curvature changes the path of the light. Liquid sample holders should be made of optical glass to minimize the effect of the sample holder on the measurement. Transmission changes with thickness and concentration. If two specimens are being compared, they must be prepared in the same way if the comparison is to be valid. This is particularly important if a numeric standard is used. A haze index can be calculated from multiple measurements of transmittance (ASTM 1003).

12.6.3
Radiometric Measurements

Spectral radiometers and radiometric colorimeters were designed to measure lamps, light sources, and visual display units. These instruments are closely related to spectrophotometers and colorimeters, but they need not supply an illuminator because the object being measured is the source of light.

Lamps and light sources can be measured either directly or indirectly by measuring the reflectance of a stable white reflecting surface being illuminated by the lamp or light source (ASTM 1341). Measuring televisions and visual display units usually requires that the emitted light be directly imaged on the optics of the instrument (ASTM 1336; ASTM 1455).

12.7
Summary

Color is an integral part of commerce and entertainment. Color perception depends upon the light source illuminating an object, the pigments and dyes used in manufacturing the object, and the eye of the observer whose impulses are translated by the brain as a color. Color is three dimensional and thus three terms (lightness, chroma, and hue) are needed to describe a color. Color is only one aspect of appearance. Members of the CIE developed a system to simulate the color perception. They standardized illuminants (mathematical light sources) and color-matching functions (simulating the eye–brain combination). Spectrophotometers are used to characterize the object completely. Tristimulus values and color coordinates can be calculated from the spectrophotometric measurements, the standardized illuminants, and the color-matching functions. Color differences between a target or standard color and a trial or batch color can be calculated from the measurements. For some situations, a single-number color scale is sufficient. For other situations, a three-component color difference is required. There are a number of equations available for calculating color differences.

An object may absorb light, scatter and reflect light, and/or transmit light. Reflectance factors are usually measured for opaque and translucent objects. Transmittance is usually measured for hazy and transparent objects. Spectrophotometers measure reflectance and/or transmittance at given wavelengths of the visible spectrum and calculations are done to determine tristimulus values and color coordinates. Colorimeters determine tristimulus values or color coordinates directly during the measurement using broad-band spectral devices. Colorimeters cannot usually detect metamerism. Fluorescent samples not only reflect light but also emit light. Special techniques are required to measure those samples. Measuring materials containing only traditional colorants and metallic flakes require instruments with multiple viewing angles. Measuring materials containing interference pigments require instruments with multiple illumination angles and multiple viewing angles. Measuring lamps and other light emitters require spectral radiometers and radiometric colorimeters.

14.1
Introduction

Molecular fluorescence is extensively used in physical, chemical, material, biological, and medical sciences as a tool of detection/analysis, visualization, investigation of local properties, diagnostics, and so on. In fact, fluorescent compounds can be used not only for mere visualization but also as probes, indicators, sensors, and tracers for providing information on local physical or chemical parameters: pressure, temperature, viscosity, polarity, pH, concentrations of ionic or neutral species, and so on (Valeur, 2002; Lakowicz, 2006; Schulman, 1985–1993; Lakowicz, 1991–2007; Valeur and Brochon, 2001; Kraayenhof and Visser, 2003; Hof, Hutterer and Fidler, 2005; Berberan-Santos, 2007; Jameson, Croney and Moens, 2003; Valeur, Berberan-Santos and Martin, 2007).

Once a molecule is excited by absorption of a photon, it can return to the ground state via many pathways (Figure 14.1). The radiative pathway, that is, emission of photons with retention of spin multiplicity, is called *fluorescence*. Another radiative pathway is *phosphorescence*, but this process first requires an intersystem crossing from the initially singlet excited state to a triplet state. This is the major distinction to be made between fluorescence and phosphorescence, and not only the fact that the decay of fluorescence intensity following light pulse excitation is generally much faster than that of phosphorescence. The nonradiative pathway of de-excitation called *internal conversion* is the direct return to the ground state without emission of photon. In the excited state, the molecule may undergo intramolecular processes: charge transfer, conformational change, and so on.

Interactions in the excited state with other molecules may lead to de-excitation: electron transfer, proton transfer, energy transfer, excimer or exciplex formation, and photochemical reaction. These de-excitation pathways may compete with fluorescence emission if they take place at a time scale comparable with the average time (called *lifetime*) during which the molecules stay in the excited state. This average time represents the *experimental time window* for observation of dynamic processes. The characteristics of fluorescence (spectrum, quantum yield, and lifetime), which are affected by any excited-state process

involving interactions of the excited molecule with its close environment, can then provide information on such a microenvironment. Figure 14.2 shows the physical and chemical parameters that characterize a microenvironment and can thus affect the fluorescence characteristics of a molecule.

In this chapter, in the second section the characteristics of fluorescence emission are described. In the third section, the effects of photoinduced intermolecular processes on fluorescence are discussed. The fourth section presents a selection of applications of molecular fluorescence in various fields.

14.2
Characteristics of Fluorescence Emission

In this section, the characteristics of fluorescence emission are described for molecules in dilute solution in the absence of any interaction with other molecules (Valeur, 2002) chap. 3. The photophysical processes resulting from such interactions are discussed in Section 14.3.

14.2.1
Radiative and Nonradiative Transitions between Electronic States

The processes that are involved in the excitation and de-excitation of a fluorescent molecule are conveniently visualized by means of the Perrin–Jablonski diagram (Figure 14.3): photon absorption, internal conversion, fluorescence, intersystem crossing, phosphorescence, and so on. Vibrational levels are associated with all electronic states. The singlet states are denoted S_0 (fundamental electronic state), $S_1, S_2, \ldots$ and the triplet states, $T_1, T_2, \ldots$ It is important to note that absorption is very fast ($\approx 10^{-15}$ seconds) with respect to all other processes (so that there is no concomitant displacement of the nuclei according to the Franck–Condon principle).

In a solution at room temperature, the majority of molecules are in the 0 (lowest) vibrational energy level of S_0. Therefore, the vertical arrows corresponding to absorption start from this level. Absorption of a photon can bring a molecule to one of the vibrational levels of $S_1, S_2, \ldots$. The subsequent possible de-excitation processes are described.

Tab. 14.1 Characteristic times involved in the excitation and de-excitation of a molecule. (From Valeur (2002).)

Process or lifetime	Characteristic time
Absorption	10^{-15} s
Vibrational relaxation	10^{-12}–10^{-10} s
Lifetime of the singlet excited state S_0	10^{-10}–10^{-7} s ⇒ fluorescence
Intersystem crossing	10^{-10}–10^{-8} s
Internal conversion	10^{-11}–10^{-9} s
Lifetime of the triplet excited state T_1	$>10^{-6}$ s ⇒ phosphorescence

The characteristic times of these processes are given in Table 14.1.

14.2.1.1 Internal Conversion

Internal conversion is a nonradiative transition between two electronic states of the same spin multiplicity.

When a molecule is excited to an energy level higher than the lowest vibrational level of the first electronic state, vibrational relaxation – and internal conversion $S_n \to S_1$ if the singlet excited state is higher than S_1 – leads the excited molecule toward the lowest vibrational level of the S_1 singlet state. The excess of vibrational energy is transferred to the solvent during collisions of the excited molecule with the surrounding solvent molecules.

Internal conversion from S_1 to S_0 is less efficient than that from S_2 to S_1 owing to the much larger energy gap between S_1 and S_0. Therefore, internal conversion from S_1 to S_0 can compete with emission of photons (fluorescence) and intersystem crossing to the triplet state.

14.2.1.2 Fluorescence

Emission of photons from an excited molecule without change in multiplicity is called *fluorescence*. Besides a few exceptions, fluorescence emission occurs from S_1 and therefore its characteristics (except polarization) do not depend on the excitation wavelength.

The fluorescence spectrum is located at higher wavelengths (lower energy) than the absorption spectrum because of the energy loss in the excited state by vibrational relaxation (Figure 14.3). The gap (expressed in wavenumbers) between the maximum of the first absorption band and the maximum of fluorescence is called *Stokes shift*.

In general, the differences between the vibrational levels are similar in the ground and excited states, so that the fluorescence spectrum often resembles the first absorption band (“mirror image” rule).

Emission of a photon is a process that is as fast as absorption of a photon ($\approx 10^{-15}$ second), but excited molecules stay in the S_1 state for a certain time (a few tens of picoseconds to a few hundreds of nanoseconds, according to the type of molecule and the medium) before emitting a photon or undergoing other de-excitation processes (internal conversion and intersystem crossing). Thus, after excitation of a population of molecules by a very short pulse of light, the fluorescence intensity decreases exponentially with a characteristic time, called *excited-state lifetime*, reflecting the average time during which the molecules stay in the S_1 excited state (10^{-10}–10^{-7} seconds) before returning to the ground state (see Section 14.2.2.1). The fluorescence intensity decay is formally comparable with a radioactive decay that is also exponential, with a characteristic time called *radioactive period*, characterizing the average lifetime of a radioelement before disintegration.

The emission of fluorescence photons is a spontaneous process. Another emission process, called *stimulated emission*, can be observed under certain conditions, for instance, in dye lasers.

14.2.1.3 Intersystem Crossing and Subsequent Processes

A third possible de-excitation process from S_1 is intersystem crossing toward the T_1 triplet state, followed by other processes (Figure 14.3).

Intersystem Crossing *Intersystem crossing* is a nonradiative transition between two isoenergetic vibrational levels belonging to electronic states of different multiplicities.

Once an excited molecule has relaxed to the 0 vibrational level of the S_1 state, it can move to the isoenergetic vibrational level of the T_n triplet state; then, vibrational relaxation brings it into the lowest vibrational level of T_1. Intersystem crossing may compete with the other pathways of de-excitation from S_1 (fluorescence and internal conversion $S_1 \rightarrow S_0$).

Crossing between states of different multiplicity is in principle forbidden, but spin–orbit coupling can be large enough to make it possible. The presence of heavy atoms (such as I, Br, Pb, etc.) favors intersystem crossing because it increases spin–orbit coupling.

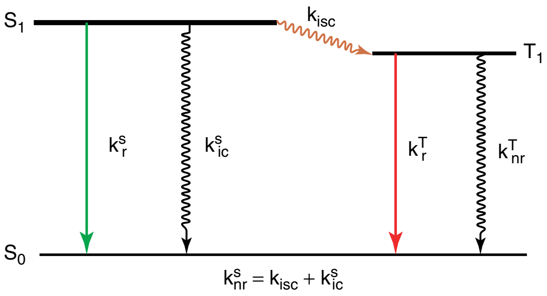
Phosphorescence versus Nonradiative De-excitation The emission of photons from the triplet state T_1 is called *phosphorescence*. Although the transition $T_1 \rightarrow S_0$ is forbidden, phosphorescence can be observed because of spin–orbit coupling. The lifetime of the triplet state T_1 is longer ($>10^{-6}$ second) than that of the singlet state S_1.

In solution at room temperature, the numerous collisions of the molecules in the triplet state state T_1 with solvent molecules favor intersystem crossing and vibrational relaxation to S_0. Nonradiative de-excitation from the triplet state T_1 is thus predominant. On the contrary, at low temperature and/or in a rigid medium, phosphorescence can be observed. Under these conditions, the lifetime of the triplet state may be long enough to observe phosphorescence on a time scale up to seconds, minutes, or even more.

The phosphorescence spectrum is located at wavelengths higher than the fluorescence spectrum (Figure 14.3) because the energy of the lowest vibrational level of the triplet state T_1 is lower than that of the singlet state S_1.

Delayed Fluorescence

- **Thermally activated delayed fluorescence**: When the energy difference between S_1 and T_1 is small and when the lifetime of T_1 is long enough, reverse intersystem crossing $T_1 \rightarrow S_1$ can occur. Thus, the emission spectrum is identical to that of normal fluorescence, but the decay



Scheme 14.1 De-excitation processes with relevant rate constants.

time constant is much longer because the molecules stay in the triplet state before emitting from S_1. The efficiency of delayed fluorescence increases with increasing temperature, because the process is thermally activated. It is generally called *delayed fluorescence of E-type* because it has been observed for the first time with eosin. E-type-delayed fluorescence is usually a weak phenomenon, but it is exceptionally intense in the case of fullerene C_{70} because the quantum yield for triplet formation is close to 1, the S_1-T_1 energy gap is quite small, and the intrinsic triplet lifetime is in the order of several milliseconds (Berberan-Santos and Garcia, 1996).

- **Triplet–triplet annihilation**:In concentrated solutions, a collision between two molecules in state T_1 can provide enough energy to allow one of them to return to state S_1. Such a triplet–triplet annihilation thus leads to a delayed fluorescence emission. It is called *delayed fluorescence of P type* because it has been observed for the first time with pyrene. The decay time constant of this type of delayed fluorescence is half the lifetime of the triplet state in dilute solution, and the intensity has a characteristic quadratic dependence with excitation light intensity.

14.2.2
Lifetimes and Quantum Yields

14.2.2.1 Excited-State Lifetimes

The various processes of de-excitation are represented in Scheme 14.1 with the relevant rate constants. The de-excitation processes that result from intermolecular interactions are not considered in this section. They are described in Section 14.3.

The rate constants are denoted as follows:

k_r^S is the rate constant for radiative deactivation $S_1 \rightarrow S_0$ with emission of fluorescence.
k_{ic}^S is the rate constant for internal conversion $S_1 \rightarrow S_0$.
k_{isc} is the rate constant for intersystem crossing.
k_r^T is the rate constant for radiative deactivation $T_1 \rightarrow S_0$ with emission of phosphorescence.
k_{nr}^T is the rate constant for nonradiative deactivation (intersystem crossing) $T_1 \rightarrow S_0$.

It is convenient to introduce the overall rate constant k_{nr}^S for nonradiative deactivation from S_1 : $k_{\mathrm{nr}}^S = k_{\mathrm{ic}}^S + k_{\mathrm{isc}}$ (14.1)

Let us consider a dilute solution of a fluorescent molecule M whose concentration is [M] (in mole per liter). A pulse of light supposed to be infinitely short (i.e., a δ-function (Dirac)) at time 0 brings a certain number of molecules M to the S_1 excited state by absorption of photons. Then, these excited molecules return to S_0 either radiatively or nonradiatively or undergo intersystem crossing. As in classical chemical kinetics, the rate of disappearance of excited molecules is expressed by the following differential equation:

$$-\frac{d[^1\mathrm{M}^*]}{dt} = \left(k_r^S + k_{\mathrm{nr}}^S\right)[^1\mathrm{M}^*] \qquad (14.2)$$

The time evolution of the concentration in excited molecules $[^1\mathrm{M}^*]$ is obtained by integration of this equation:

$$[^1\mathrm{M}^*] = [^1\mathrm{M}^*]_0 \exp\left(-\frac{t}{\tau_S}\right) \qquad (14.3)$$

where $[^1\mathrm{M}^*]_0$ is the concentration in excited molecules at time 0 resulting from pulse light excitation, and τ_S is the lifetime of excited state S_1, given as

$$\tau_S = \frac{1}{k_r^S + k_{\mathrm{nr}}^S} \qquad (14.4)$$

The fluorescence intensity is defined as the amount of photons (in mol, or its equivalent, in einstein; 1 einstein = 1 mol of photons) emitted per unit time (second) and per unit volume of solution (liter) according to

$$\mathrm{M}^* \xrightarrow{k_r^S} \mathrm{M} + \text{photon} \qquad (14.5)$$

The fluorescence intensity i_F at time t after excitation by a very short pulse of light at time 0 is proportional, at any time, to the instantaneous concentration of molecules still excited $[^1\mathrm{M}^*]$; the proportionality factor is the rate constant for radiative de-excitation k_r^S:

$$\begin{aligned} i_F(t) &= k_r^S[^1\mathrm{M}^*] \\ &= k_r^S[^1\mathrm{M}^*]_0 \exp\left(-\frac{t}{\tau_S}\right) \end{aligned} \qquad (14.6)$$

$i_F(t)$, the *δ-pulse response* of the system, decreases according to a single exponential.

In practice, the measured signal I_F representing the fluorescence intensity is proportional to i_F, the proportionality factor depending on instrumental conditions. The numerical value of I_F is thus generally obtained in an arbitrary scale.

If the only way of de-excitation from S_1 to S_0 was fluorescence emission, the lifetime would be $1/k_r^S$: it is called *radiative lifetime* (in preference to *natural lifetime*) and denoted τ_r.

The lifetime of a homogeneous population of fluorophores is in principle independent of the excitation wavelength because internal conversion and vibrational relaxation are always very fast in solution and emission arises from the lowest vibrational level of state S_1.

If a fraction of excited molecules reach the triplet state from which they return to the ground state either radiatively or nonradiatively, the concentration of molecules in the triplet state decays exponentially with a time constant τ_T representing the lifetime of the triplet state:

$$\tau_{\mathrm{T}} = \frac{1}{k_r^T + k_{\mathrm{nr}}^T} \qquad (14.7)$$

14.2.2.2 Quantum Yields

The *fluorescence quantum yield* Φ_F is the fraction of excited molecules that return to the ground state S_0 with emission of fluorescence photons.

$$\Phi_F = \frac{k_r^S}{k_r^S + k_{\text{nr}}^S} = k_r^S \tau_S \tag{14.8}$$

In other words, the fluorescence quantum yield is the ratio of the number of emitted photons (over the whole duration of the decay) and the number of absorbed photons. According to Eq. (14.6), the ratio of the δ-pulse response $i_F(t)$ and the number of absorbed photons is given by

$$\frac{i_F(t)}{[{}^1\text{M}^*]_0} = k_r^S \exp\left(-\frac{t}{\tau_S}\right) \tag{14.9}$$

The fluorescence quantum yield is then obtained by integration of this relation over the whole duration of the decay (mathematically from 0 to infinity):

$$\frac{1}{[{}^1\text{M}^*]_0} \int_0^\infty i_F(t) = k_r^S \tau_S = \Phi_F \tag{14.10}$$

The quantum yields of intersystem crossing (Φ_{isc}) and phosphorescence (Φ_P) are given by

$$\Phi_{\text{isc}} = \frac{k_{\text{isc}}}{k_r^S + k_{\text{nr}}^S} = k_{\text{isc}}^S \tau_S \tag{14.11}$$

$$\Phi_{\text{P}} = \frac{k_r^T}{k_r^T + k_{\text{nr}}^T} \Phi_{\text{isc}} \tag{14.12}$$

Using the radiative lifetime, as previously defined, the fluorescence quantum yield can also be written as

$$\Phi_F = \frac{\tau_S}{\tau_r} \tag{14.13}$$

It is interesting to note that when the fluorescence quantum yield and the excited-state lifetime of a fluorophore are measured under the same conditions, the nonradiative and radiative rate constants can be easily calculated by means of the following relations:

$$k_r^S = \frac{\Phi_F}{\tau_S}, \quad k_r^S = \frac{1}{\tau_S}(1 - \Phi_F) \tag{14.14}$$

14.2.3
Emission and Excitation Spectra

14.2.3.1 Emission Spectra

The variations in fluorescence intensity as a function of the observation wavelength λ_E, for a fixed excitation wavelength λ_F, represents the *emission spectrum*. It is convenient to express the steady-state fluorescence intensity (i.e., under continuous illumination) per absorbed photon as a function of the wavelength of the emitted photons, denoted $F_\lambda(\lambda_F)$ (in m^{-1} or nm^{-1}), normalized so that the integral over the whole spectrum is equal to the fluorescence quantum yield Φ_F:

$$\int_0^\infty F_\lambda(\lambda_F) d\lambda_F = \Phi_F \tag{14.15}$$

$F_\lambda(\lambda_F)$ represents the *fluorescence spectrum* or *emission spectrum*: it reflects the distribution of the probability of the various transitions from the lowest vibrational level of S_1 to the various vibrational levels of S_0.

Assuming that the number of absorbed photons follows the Beer–Lambert law, the intensity of the transmitted light is given by

$$I_T(\lambda_E) = I_0(\lambda_E) \exp\left[-2.3\, \varepsilon(\lambda_E)\, l\, c\right] \tag{14.16}$$

where $I_0(\lambda_E)$ is the intensity of the incident light, $\varepsilon(\lambda_E)$ denotes the molar absorption coefficient of the fluorophore at wavelength λ_E (in liter per mole per centimeter), l is the optical path in the sample (in centimeter), and c is the concentration (in mol per liter).

The quantity $\varepsilon(\lambda_E)lc$ represents the absorbance $A(\lambda_E)$ at wavelength λ_E.

The difference between the intensity of the incident light $I_0(\lambda_E)$ and the intensity of the transmitted light $I_T(\lambda_E)$ represents the absorbed intensity $I_A(\lambda_E)$.

The fluorescence intensity can be written as

$$I_F(\lambda_E, \lambda_F) = k\ F_\lambda(\lambda_F)\ I_A(\lambda_E) \qquad (14.17)$$

where k is a proportionality factor that depends on several parameters and in particular on the optical configuration for observation (i.e., the solid angle through which the instrument collects fluorescence that is, in fact, emitted in all directions) and on the bandwidth of the monochromators (i.e., the widths of the entrance and exit slits).

Finally, the general expression for the fluorescence intensity is the following:

$$\begin{aligned} I_F(\lambda_E, \lambda_F) &= k\ F_\lambda(\lambda_F)\ I_0(\lambda_E) \\ &\quad \times \{1 - \exp[-2.3\varepsilon(\lambda_E)lc]\} \end{aligned} \qquad (14.18)$$

In highly diluted solutions, the exponential term can be approximated to $1 - 2.3\varepsilon lc$, so that the fluorescence intensity becomes proportional to the concentration:

$$\begin{aligned} I_F(\lambda_E, \lambda_F) &\cong k\ F_\lambda(\lambda_F)\ I_0(\lambda_E) \\ &\quad \times [2.3\varepsilon(\lambda_E)lc] \\ &= 2.3\ k\ F_\lambda(\lambda_F)\ I_0(\lambda_E)\ A(\lambda_E) \end{aligned} \qquad (14.19)$$

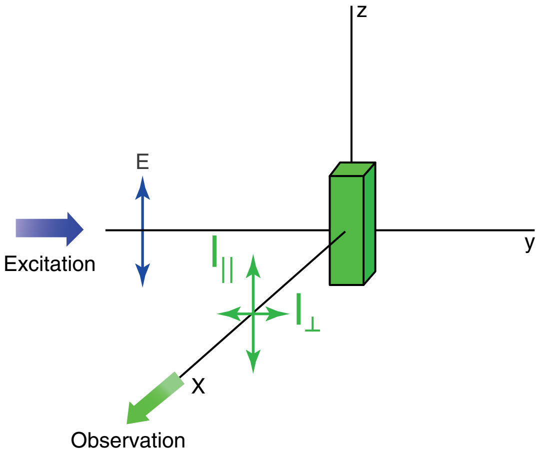
It should be emphasized that such a proportionality is valid only for low absorbances. Deviation from a linear variation increases with increasing absorbance.

In practice, the variations in I_F measured as a function of wavelength λ_F, for a fixed excitation wavelength λ_E, reflect the variations in $F_\lambda(\lambda_F)$ and thus provide the fluorescence spectrum. Because the proportionality factor k is generally unknown, the numerical value of the measured intensity I_F has no meaning, and generally speaking, I_F is expressed in arbitrary units. It should be noted that k depends on the wavelength because the transmission of the monochromator and the sensitivity of the detector are wavelength dependent. Therefore, correction of spectra is necessary for quantitative measurements.

Spectrofluorometry is a very sensitive technique – up to 1000 times more sensitive than spectrophotometry. This is because the fluorescence intensity is measured above a low background level, whereas in the measurement of low absorbances, two large signals that are slightly different are compared. Thanks to outstanding progress in instrumentation, it is now possible in some cases to even detect a single fluorescent molecule.

14.2.3.2 **Excitation Spectra**

The variations in fluorescence intensity as a function of the excitation wavelength λ_E, for a fixed observation wavelength λ_F, represent the *excitation spectrum*. In Eq. (14.19), when the observation wavelength λ_F is fixed, the variations in fluorescence intensity reflect the evolution of the product $I_0(\lambda_E)\ A(\lambda_E)$. Provided that the wavelength dependence of the incident light $I_0(\lambda_E)$ is compensated, the sole term to be taken into consideration is $A(\lambda_E)$, which represents the absorption spectrum. The corrected excitation spectrum is thus identical in shape with the absorption spectrum provided that there is a single species in the ground state.



Scheme 14.2 Usual optical configuration for fluorescence anisotropy measurements.

In contrast, when several species are present, or when a sole species exists in different forms in the ground state (aggregates, complexes, tautomeric forms, etc.), the excitation and absorption spectra are no longer superimposable. Comparison between absorption and emission spectra often provides useful information.

14.2.3.3 Stokes Shift

The *Stokes shift* is the difference, expressed in wavenumbers, between the maximum of the first absorption band and the maximum of fluorescence spectrum: $\Delta\overline{v} = \overline{v}_a - \overline{v}_f$.

This parameter depends on the structure of the molecule and on its microenvironment. For instance, when the dipole moment of a fluorescent molecule is higher in the excited state than in the ground state, the Stokes shift increases with solvent polarity. This dependence is a means to estimate the polarity of an unknown environment.

From the practical point of view, the detection of a fluorescent species is easier when the Stokes shift is larger.

14.2.4
Fluorescence Anisotropy

Fluorescence anisotropy, also called *emission anisotropy*, is used to characterize the polarization of fluorescence resulting from photoselection when an assembly of molecules is illuminated by a linearly polarized light (Valeur, 2002 Chapter 5). It is defined as

$$r = \frac{I_{||} - I_{\perp}}{I_{||} + 2I_{\perp}} \qquad (14.20)$$

where $I_{||}$ and $I_{\perp}$ are the intensities measured with a linear polarizer for emission parallel and perpendicular, respectively, to the electric vector of linearly polarized incident light (which is often vertical) (Scheme 14.2). The quantity $I_{||} + 2I_{\perp}$ is proportional to the total fluorescence intensity I.

Fluorescence polarization may also be characterized by the polarization ratio, also called the *degree of polarization*, defined as

$$p = \frac{I_{||} - I_{\perp}}{I_{||} + I_{\perp}} \qquad (14.21)$$

The relation between r and p is

$$r = \frac{2p}{(3-p)} \tag{14.22}$$

For parallel absorbing and emitting transition moments, the (theoretical) values are $(r, p) = (1/2, 2/5)$; when the transition moments are perpendicular, the values are $(r, p) = (-1/3, -1/5)$.

In many cases, it is preferable to use emission anisotropy because it is additive; the overall contribution of n components r_i, each contributing to the total fluorescence intensity with a fraction $f_i = I_i/I$, is given by

$$r = \sum_{i=1}^{n} f_i r_i \quad \text{with} \quad \sum_{i=1}^{n} f_i = 1 \tag{14.23}$$

On continuous illumination, the measured emission anisotropy is called *steady-state emission anisotropy* and is given by

$$\bar{r} = \frac{\int_0^\infty r(t) I(t) dt}{\int_0^\infty I(t) dt} \tag{14.24}$$

where $r(t)$ is the instantaneous anisotropy and $I(t)$ is the fluorescence intensity at time t following a δ-pulse excitation.

The term *fundamental emission anisotropy* describes a situation in which no depolarizing events occur subsequent to the initial formation of the emitting state, such as those caused by rotational diffusion or energy transfer. It also assumes that there is no overlap between differently polarized transitions. The (theoretical) value of the fundamental emission anisotropy depends on the angle α between the absorption and emission transition moments according to the relation $r_0 =< 3\cos^2\alpha > /5$ where $<>$ denotes an average over the orientations of the photoselected molecules. r_0 can take on values ranging from $-1/5$ for $\alpha = 90°$ (perpendicular transition moments) to $2/5$ for $\alpha = 0°$ (parallel transition moments). In spite of the severe assumptions, the expression is frequently used to determine relative transition moment angles.

In time-resolved fluorescence with δ-pulse excitation, the theoretical value at time zero is identified with the fundamental emission anisotropy.

14.3
Effects of Intermolecular Photophysical Processes on Fluorescence

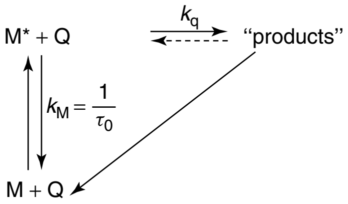
14.3.1
Main Photoinduced Intermolecular Processes

The interaction between an excited molecule M* and another molecule Q may occur of course as long as M is in its excited state (Valeur, 2002, Chapter 4). The key parameter is thus the lifetime of the excited state of M*, which is the experimental time window through which processes of similar duration, and competing with the intrinsic de-excitation, can be observed. It is subsequently denoted τ_0 and is given by Eq. (14.4) rewritten as

$$\tau_0 = \frac{1}{k_r + k_{\mathrm{nr}}} \tag{14.25}$$

Scheme 14.3 illustrates the competition between the intermolecular interaction characterized by the rate constant k_q for the bimolecular process and the intrinsic de-excitation of M* whose rate constant is $k_M = 1/\tau_0$.

The main intermolecular photophysical processes are presented in Table 14.2.



Scheme 14.3 Competition in the excited state between intrinsic de-excitation and interaction with another molecule Q.

Tab. 14.2 Main photophysical processes. (From Valeur (2002).)

Photophysical process	$M^* + Q \rightarrow$ products	**Donor**	**Acceptor**
Collision with a heavy atom (e.g., I^-, Br in CBr_4) or a paramagnetic species (e.g., O_2, NO)	$M^* + Q \rightarrow M + Q + \text{heat}$		
Electron transfer	$D^* + A \rightarrow D^{\cdot+} + A^{\cdot-}$	*D**	A
	$A^* + D \rightarrow A^{\cdot-} + D^{\cdot+}$	*D*	A*
Excimer formation	$M^* + M \rightarrow (MM)^*$		
Exciplex formation	$D^* + A \rightarrow (DA)^*$	D*	A
	$A^* + D \rightarrow (DA)^*$	D	A*
Proton transfer	$AH^* + B \rightarrow A^{-*} + BH^+$	AH*	B
	$B^* + AH \rightarrow BH^{+*} + A^-$	AH	B*
Energy transfer			
Heterotransfer	$D^* + A \rightarrow D + A^*$	D*	A
Homotransfer	$M^* + M \rightarrow M + M^*$	M*	M

It should be noted that most of them involve a fast transfer process from a donor to an acceptor: electron transfer, proton transfer, and energy transfer.

Because of the additional way of de-excitation due to the interaction with Q, the fluorescence quantum yield of M is decreased. The loss of fluorescence intensity is called *fluorescence quenching* irrespective of the nature of the competing intermolecular process and even if this process leads to a fluorescent species (the term quenching applies only to the initially excited molecule). Another consequence is the faster decrease in the fluorescence intensity after excitation by a light pulse.

If Q is in large excess, the excited-state process occurs under nondiffusive conditions. However, if Q is not in large excess and if mutual approach of M* and Q is possible during the excited-state lifetime, the bimolecular excited-state process is then *diffusion controlled*, and the rate constant is time dependent.

14.3.2
Fluorescence Quenching

14.3.2.1 Dynamic Quenching

Stern–Volmer Kinetics In the first approach, let us assume, that the experimental quenching rate constant k_q is time independent. According to the simplified Scheme 14.3, the time evolution of the concentration of M* following a δ-pulse excitation obeys the following differential equation:

$$\frac{d[\mathrm{M}^*]}{dt} = -\left(k_M + k_q[\mathrm{Q}]\right)\,[\mathrm{M}^*] = -\left(\frac{1}{\tau_0} + k_q[\mathrm{Q}]\right)\,[\mathrm{M}^*] \tag{14.26}$$

With the initial condition $[\mathrm{M}^*] = [\mathrm{M}^*]_0$ at $t = 0$, integration of this differential equation leads to

$$[\mathrm{M}^*] = [\mathrm{M}^*]_0\,\exp\left\{-\left(\frac{1}{\tau_0} + k_q[\mathrm{Q}]\right)t\right\} \tag{14.27}$$

The fluorescence intensity is obtained by multiplying the concentration of M* by the radiative rate constant:

$$\begin{aligned} i(t) &= k_r[\mathrm{M}^*] \\ &= k_r[\mathrm{M}^*]_0\,\exp\left\{-\left(\frac{1}{\tau_0} + k_q[\mathrm{Q}]\right)t\right\} \\ &= i(0)\,\exp\left\{-\left(\frac{1}{\tau_0} + k_q[\mathrm{Q}]\right)\,t\right\} \end{aligned} \tag{14.28}$$

where k_r is the radiative rate constant of M*. The fluorescence decay is thus a single exponential whose time constant is given by

$$\tau = \frac{1}{\dfrac{1}{\tau_0} + k_q\,[\mathrm{Q}]} = \frac{\tau_0}{1 + k_q\,\tau_0\,[\mathrm{Q}]} \tag{14.29}$$

Hence,

$$\frac{\tau_0}{\tau} = 1 + k_q\,\tau_0\,[\mathrm{Q}] \tag{14.30}$$

The fluorescence quantum yields in the absence and in the presence of quencher are, respectively,

$$\Phi_0 = k_r\,\tau_0 \tag{14.31}$$

and

$$\Phi = \frac{k}{k_r + k_{\mathrm{nr}} + k_q[\mathrm{Q}]} = \frac{k_r}{1/\tau_0 + k_q[\mathrm{Q}]} \tag{14.32}$$

The ratio leads to the *Stern–Volmer relation*:

$$\frac{\Phi_0}{\Phi} = \frac{I_0}{I} = 1 + k_q\,\tau_0[\mathrm{Q}] = 1 + K_{\mathrm{SV}}[\mathrm{Q}] \tag{14.33}$$

where I_0 and I are the steady-state fluorescence intensities (for a couple of wavelengths λ_E and λ_F) in the absence and in the presence of quencher, respectively. $K_{\mathrm{SV}} = k_q\tau_0$ is the Stern–Volmer constant. Generally, the ratio I_0/I is plotted versus the quencher concentration (Stern–Volmer plot). If the variation is found to be linear, the slope yields the Stern–Volmer constant. Then, k_q can be calculated if the excited-state lifetime in the absence of quencher is known.

Time-resolved experiments in the absence and in the presence of quencher allow us to check whether the fluorescence decay is, in fact, a single exponential and provide directly the value of k_q.

Two cases are to be distinguished:

- If the bimolecular process is not diffusion-limited: $k_q = pk_1$, where p is the probability of reaction for the encounter pair (often called efficiency), and k_1 is the diffusional rate constant.
- If the bimolecular process is diffusion-limited: k_q is identical to the diffusional rate constant k_1, which can be written in the following simplified form (proposed for the first

time by Smoluchowski):

$$k_1 = 4\pi N R_c D \quad (\text{in l mol}^{-1}\ \text{s}^{-1}) \tag{14.34}$$

where R_c is the distance of closest approach (in centimeter), D is the mutual diffusion coefficient (in square centimeter per second), N is equal to $N_A/1000$, N_A being Avogadro's constant. The distance of closest approach is generally taken as the sum of the radii of the two molecules (R_M for the fluorophore and R_Q for the quencher). The mutual diffusion coefficient D is the sum of the translational diffusion coefficients of the two species, D_M and D_Q, which can be expressed by the Stokes–Einstein relation:

$$D = D_M + D_Q = \frac{k\,T}{f\,\pi\,\eta}\left(\frac{1}{R_M} + \frac{1}{R_Q}\right) \tag{14.35}$$

where k is Boltzmann's constant, η is the viscosity of the medium, and f is a coefficient that is equal to 6 for "stick" boundary conditions and 4 for "slip" boundary conditions.

If R_M and R_Q are of the same order, the diffusional rate constant is approximately equal to $8RT/3\eta$.

In liquids, k_1 is about 10^9–10^{10} l mol^{-1} s^{-1}. The diffusion coefficient of molecules in the usual solvents at room temperature is generally of the order of 10^{-5} cm^2 s^{-1}.

Quenching of fluorescence (and phosphorescence) by dioxygen deserves attention because it is always present in solution. The effect on quantum yields and lifetimes strongly depends on the nature of the compound and the medium. Oxygen quenching is a collisional process and is therefore diffusion controlled. Consequently, compounds of long lifetime, such as naphthalene and pyrene, are particularly sensitive to the presence of oxygen. Moreover, oxygen quenching is less efficient in media of high viscosity. Oxygen quenching can be reduced by bubbling with nitrogen or argon; the most efficient method is, however, to use the freeze-pump-thaw technique (especially for phosphorescence studies).

Transient Effects In reality, the diffusional rate constant is time dependent and should be written as $k_1(t)$. Several models have been developed to express the time-dependent rate constant. Using Smoluchowski's theory, the fluorescence decay can be written in the following form:

$$i(t) = i(0)\ \exp\left(-at - 2b\sqrt{t}\right) \tag{14.36}$$

where

$$a = \frac{1}{\tau_0} + 4\pi N R_c D[\mathrm{Q}] \tag{14.37}$$

$$b = 4\sqrt{\pi D} N R_c^2 [\mathrm{Q}] \tag{14.38}$$

It should be noted that, in media of low viscosity, the transient term is significant only at short times (less than 100 picoseconds at viscosities similar to that of water) and can be neglected, whereas in viscous media, this term cannot be ignored (the fluorescence decay is then no longer a single exponential).

14.3.2.2 Static Quenching

Sphere of Effective Quenching In rigid matrices or in media so viscous that M* and Q cannot change their positions in space relative to one another during the excited-state lifetime of M*, Perrin has proposed a model in which quenching of a fluorophore is assumed to be complete if a quencher molecule Q is located inside a sphere (called *sphere of effective quenching, active sphere,* or *quenching sphere*) of volume V_q surrounding the fluorophore M. If a quencher is outside the active sphere, it has no effect at all on M. Therefore, the fluorescence intensity of the solution is decreased by the addition of Q, but the fluorescence decay after pulse excitation is unaffected.

According to this model, the ratio I_0/I is given as

$$\frac{I_0}{I} = \exp(V_q N[\mathrm{Q}]) \tag{14.39}$$

At low quencher concentrations, $\exp(V_q N[\mathrm{Q}]) \cong 1 + V_q N[\mathrm{Q}]$: the plot of I_0/I is thus almost linear (as in the case of the Stern–Volmer plot), but at high concentrations, it shows an upward curvature.

A plot of $\ln(I_0/I)$ versus [Q] yields V_q. The values of $V_q N$ are often found to be in the range of 1–3 l mol^{-1}. This corresponds to a quenching sphere radius of about 10 Å, which is slightly larger than the van der Waals contact distance between M and Q.

Perrin's model has been used in particular for the interpretation of nonradiative energy transfer in rigid media.

Formation of a Ground-State Nonfluorescent Complex In some cases, M can form a nonfluorescent 1 : 1 complex according to the equilibrium

$$\mathrm{M} + \mathrm{Q} \rightleftarrows \mathrm{MQ} \tag{14.40}$$

The stability constant of the complex is

$$K_S = \frac{[\mathrm{MQ}]}{[\mathrm{M}][\mathrm{Q}]} \tag{14.41}$$

The excited-state lifetime of the uncomplexed fluorophores M is unaffected. The fluorescence intensity of the solution decreases with the addition of Q, but the fluorescence decay after pulse excitation is unaffected, in contrast to dynamic quenching. Quinones, hydroquinones, purines, and pyrimidines are well-known examples of molecules responsible for static quenching.

Using the mass conservation law (where $[\mathrm{M}]_0$ is the total concentration of M)

$$[\mathrm{M}]_0 = [\mathrm{M}] + [\mathrm{MQ}] \tag{14.42}$$

the fraction of uncomplexed fluorophores is

$$\frac{[\mathrm{M}]}{[\mathrm{M}]_0} = \frac{1}{1 + K_S\,[\mathrm{Q}]} \tag{14.43}$$

In dilute solutions, the fluorescence intensities being proportional to the concentrations, we obtain

$$\frac{I_0}{I} = 1 + K_S\,[\mathrm{Q}] \tag{14.44}$$

A linear relation is thus obtained, as in the case of Stern–Volmer plot (Eq. (14.33)), but there is no change in excited-state lifetime for static quenching, whereas in the case of dynamic quenching, the ratio I_0/I is proportional to the ratio τ_0/τ of the lifetimes.

Simultaneous Dynamic and Static Quenching When both static and dynamic quenching occur simultaneously, a deviation of the plot of I_0/I versus [Q] from linearity is observed.

In the case of static quenching resulting from the formation of a nonfluorescent complex, the ratio I_0/I obtained for dynamic quenching must be multiplied by the fraction of fluorescent molecules (i.e., uncomplexed):

$$\frac{I}{I_0} = \left[\frac{I}{I_0}\right]_{\text{dyn}} \times \frac{[\text{M}]}{[\text{M}]_0} \qquad (14.45)$$

Using Eqs (14.33) and (14.43), the ratio I_0/I is given by

$$\begin{aligned}\frac{I_0}{I} &= (1 + K_{\text{SV}}\,[\text{Q}])\,(1 + K_S\,[\text{Q}])\\ &= 1 + (K_{\text{SV}} + K_S)\,[\text{Q}]\\ &\quad + K_{\text{SV}}\,K_S\,[\text{Q}]^2 \qquad (14.46)\end{aligned}$$

An upward curvature is thus observed. K_{SV} and K_S can be determined by curve fitting using Eq. (14.46), or alternatively from the plot of $(I_0/I - 1)/[\text{Q}]$ versus [Q], which should be linear.

Alternatively, using the model of sphere of effective quenching, we obtain the following relation:

$$\frac{I}{I_0} = (1 + K_{\text{SV}}[\text{Q}])\ \exp(V_q N_{\text{A}}[\text{Q}]) \qquad (14.47)$$

It should be noted that an upward curvature can also be due to transient effects, which may superimpose the effect of static quenching.

For unambiguous assignment of the dynamic and static quenching constants, it is recommended to carry out time-resolved experiments.

14.3.3
Photoinduced Electron Transfer

Photoinduced electron transfer (PET) is involved in many organic photochemical reactions and is often responsible for fluorescence quenching. It plays a major role in photosynthesis and in artificial systems for the conversion of solar energy based on photoinduced charge separation.

It is well known that the oxidative and reductive properties of molecules can be enhanced in the excited state. Oxydative and reductive electron transfer processes occur according to the following reactions:

$$\text{D}^* + \text{A} \rightarrow \text{D}^{\cdot+} + \text{A}^{\cdot-} \qquad (14.48)$$

$$\text{A}^* + \text{D} \rightarrow \text{A}^{\cdot-} + \text{D}^{\cdot+} \qquad (14.49)$$

Examples of donor and acceptor molecules are given in Table 14.3.

In the gas phase, the variations in standard free enthalpy ΔG^0 for the above reactions can be expressed by using the redox potentials E^0 and the excitation energy ΔE_{00}, that is, the difference in

Tab. 14.3 Examples of electron donors and acceptors. (From Valeur (2002).)

Electron donors	**Electron acceptors**
	$X = H-, (CH_3)_2N-, CH_3O-, HS-$ Naphthalene Anthracene Phenanthrene Pyrene Perylene	 $Y = -CN, -C(=O)-R, -NO_2$ 9,10-dicyanoanthracene

energy between the lowest vibrational levels of the excited state and the ground state:

$$\begin{aligned}\Delta G^0 &= E^0_{\mathrm{D^{\cdot+}/D^*}} - E^0_{\mathrm{A/A^{\cdot-}}}\\ &= E^0_{\mathrm{D^{\cdot+}/D}} - E^0_{\mathrm{A/A^{\cdot-}}} - \Delta E_0(\mathrm{D}) \quad (14.50)\end{aligned}$$

$$\begin{aligned}\Delta G^0 &= E^0_{\mathrm{D^{\cdot+}/D}} - E^0_{\mathrm{A^*/A^{\cdot-}}}\\ &= E^0_{\mathrm{D^{\cdot+}/D}} - E^0_{\mathrm{A/A^{\cdot-}}} - \Delta E_0(\mathrm{A}) \quad (14.51)\end{aligned}$$

These equations are called *Rehm–Weller equations*. If the redox potentials are expressed in volts, then ΔG^0 is given in volts. Conversion into joule per mole requires multiplication by the Faraday constant ($F = 96\,500$ C mol^{-1}).

In solution, two terms should be added for taking into account the solvation effect (enthalpic term ΔH_{solv}) and the Coulombic energy of the formed ion pair:

$$\Delta G^0 = E^0_{\mathrm{D^{\cdot+}/D}} - E^0_{\mathrm{A/A^{\cdot-}}} - \Delta E_0(\mathrm{D}) - \Delta H_{\mathrm{solv}} - \frac{e^2}{4\pi\varepsilon r} \quad (14.52)$$

$$\Delta G^0 = E^0_{\mathrm{D^{\cdot+}/D}} - E^0_{\mathrm{A/A^{\cdot-}}} - \Delta E_0(\mathrm{A}) - \Delta H_{\mathrm{solv}} - \frac{e^2}{4\pi\varepsilon r} \quad (14.53)$$

where e is the electron charge, ε is the dielectric constant of the solvent, and r is the distance between the two ions.

The redox potentials can be determined by electrochemical measurements or by theoretical calculations using the energy levels of the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO).

14.3.4
Formation of Excimers and Exciplexes

Excimers are formed by collision of an excited molecule and an identical unexcited molecule:

$$\mathrm{M^* + M} \rightleftarrows \mathrm{(MM)^*}\ (\text{or } \mathrm{E^*}) \quad (14.54)$$

Excimers are dimers in the excited state (the term excimer results form the contraction of "*exci*ted di*mer*"). The notation (MM)* expresses that the excitation energy is delocalized over the two moieties.

Exciplexes are formed by collision of an excited molecule (electron donor or acceptor) with an unlike unexcited molecule (electron acceptor or donor):

$$\mathrm{D^* + A} \rightleftarrows \mathrm{(DA)^*} \quad (14.55)$$

$$\mathrm{A^* + D} \rightleftarrows \mathrm{(DA)^*} \quad (14.56)$$

Exciplexes are excited-state complexes (the term exciplex comes from "*exci*ted com*plex*").

Excimer and exciplex formations are diffusion-controlled processes. The photophysical effects are thus detected at relatively high concentrations of the species so that a sufficient number of collisions can occur during the excited-state lifetime. Temperature and viscosity are important parameters.

14.3.4.1 **Excimers**

Many aromatic hydrocarbons such as naphthalene or pyrene can form excimers in which the two aromatic rings are facing at a distance of approximately 3–4 Å. The fluorescence band corresponding to excimer is located at wavelengths higher than that of the monomer and does not show vibronic bands because the lowest state is dissociative and can thus be considered as a continuum (Figure 14.4).

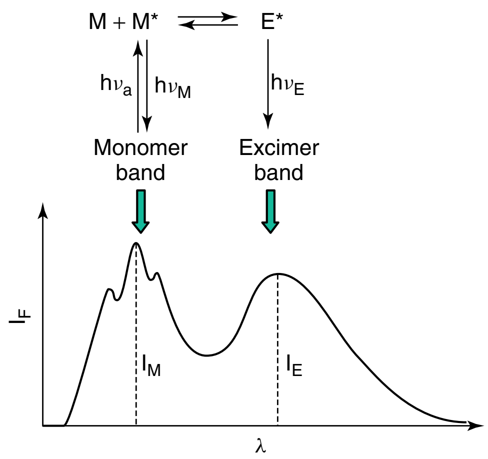


Fig. 14.4 Excimer formation and typical fluorescence spectrum showing the monomer and excimer bands. (Reproduced with permission from Valeur (2002). Copyright Wiley-VCH Verlag GmbH & Co. KGaA.)

Let k_M and k_E be the reciprocals of the excited-state lifetimes of the monomer and the excimer, respectively, and k_1 and k_{-1} are rate constants for the excimer formation and dissociation processes, respectively (Scheme 14.4).

The time evolution of the fluorescence intensity of the monomer M and the excimer E following a δ-pulse excitation can be obtained from the differential equations expressing the evolution of the species according to Scheme 14.4:

$$\frac{d[\mathrm{M}^*]}{dt} = -k_M\,[\mathrm{M}^*] - k_1[\mathrm{M}][\mathrm{M}^*] + k^*_{-1}[\mathrm{E}^*] \qquad (14.57)$$

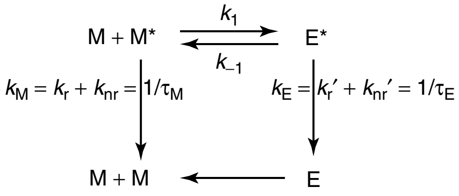
$$\frac{\mathrm{d}[\mathrm{E}^*]}{\mathrm{d}t} = k_1\,[\mathrm{M}][\mathrm{M}^*] - (k_\mathrm{D} + k_{-1})\,[\mathrm{E}^*] \qquad (14.58)$$

Formation of excimer E* is a diffusion-controlled process. Under the approximation that k_1 is time independent, the δ-pulse responses, under the following initial conditions (at $t = 0$), $[\mathrm{M}^*] = [\mathrm{M}^*]_0$ and $[\mathrm{E}^*]_0 = 0$, are

$$\begin{aligned} i_M(t) &= k_r\,[\mathrm{M}^*] \\ &= \frac{k_r\,[\mathrm{M}^*]_0}{\beta_1 - \beta_2}\big[(X - \beta_2)e^{-\beta_1 t} \\ &\qquad + (\beta_1 - X)e^{-\beta_2 t}\big] \end{aligned} \qquad (14.59)$$

$$\begin{aligned} i_E(t) &= k_r\,k_1\,[\mathrm{E}^*] \\ &= \frac{k_r\,k_1\,[\mathrm{M}][\mathrm{M}^*]_0}{\beta_1 - \beta_2}\big[e^{-\beta_2 t} - e^{-\beta_1 t}\big] \end{aligned} \qquad (14.60)$$

where k_r and $k_r{}'$ are the radiative rate constants of M* and E*, respectively, and



Scheme 14.4 Excimer formation and relevant rate constants.

β_1 and β_2 are given by

$$\beta_{2,1} = \frac{1}{2}\Big\{X + Y \pm \big[(Y - X)^2 + 4\,k_1\,k_{-1}[\mathrm{M}]\big]^{1/2}\Big\} \tag{14.61}$$

where

$$X = k_M + k_1\,[\mathrm{M}] = \frac{1}{\tau_M} + k_1\,[\mathrm{M}] \quad \text{and}$$
$$Y = k_E + k_{-1} = 1/\tau_E + k_{-1} \tag{14.62}$$

The decay of monomer emission is thus a sum of two exponentials, whereas the time evolution of the excimer emission is a difference of two exponentials in which the preexponential factors are of opposite signs. The time constants are the same in the expressions of $i_M(t)$ and $i_E(t)$ (β_1 and β_2 are the eigenvalues of the system). The negative term in $i_E(t)$ represents the rise in intensity corresponding to excimer formation; the fluorescence intensity starts indeed from zero since excimer does not absorb light and can only be formed from the monomer.

If the dissociation of the excimer cannot occur during the lifetime of the excited state ($k_{-1} = 0$), we have

$$i_M(t) = k_r\,[\mathrm{M}^*]_0\,e^{-Xt} \tag{14.63}$$

$$i_E(t) = \frac{k_r\,k_1\,[\mathrm{M}][\mathrm{M}^*]_0}{X - k_E}\left[e^{-k_E t} - e^{-Xt}\right] \tag{14.64}$$

In this case, the fluorescence decay of the monomer is a single exponential with a decay time ($1/X$) equal to the risetime of the excimer fluorescence.

The steady-state fluorescence intensities are obtained by integration of Eqs (14.59) and (14.60). The ratio of the fluorescence intensities of the excimer and monomer bands I_E/I_M (Figure 14.4) is often used for characterizing the efficiency of excimer formation. This ratio is given as

$$\frac{I_E}{I_M} = \frac{k'_r}{k_r}\frac{k_1[\mathrm{M}]}{k_{-1} + 1/\tau_E} \tag{14.65}$$

Under conditions where the dissociation rate of the excimer is slow with respect to de-excitation, this equation is reduced to

$$\frac{I_E}{I_M} = \frac{k'_r}{k_r}\tau_E k_1[\mathrm{M}] \tag{14.66}$$

These equations show that the ratio I_E/I_M is proportional to the rate constant k_1 for excimer formation.

When the two monomers are linked by a short flexible chain, intramolecular excimers can be formed. This process is still diffusion controlled, but is no longer translational; it requires a close approach between the two molecules via internal rotations during the excited-state lifetime. Because intramolecular excimer formation is independent of the total concentration, Eqs (14.59)–(14.66) are still valid provided that $k_1[\mathrm{M}]$ is replaced by k_1.

Assuming that the Stokes–Einstein relation (Eq. (14.35)) is valid, k_1 is proportional to the ratio T/η, η being the viscosity of the medium. A well-known example of application is the estimation of the local fluidity of a medium (see Section 14.4.2.1, Method Based on Intramolecular Excimer Formation).

Another example of application is the determination of micellar aggregation numbers based on self-quenching of pyrene by excimer formation within micelles (Kalyanasundaran, 1987).

14.3.4.2 Exciplexes

The kinetic scheme for exciplex formation is slightly similar to that of excimer formation. Formation of an exciplex with anthracene and *N*,*N*-diethylaniline is a classical example: it results from the transfer of an electron from an amine molecule to an excited anthracene molecule. The quenching of anthracene fluorescence in a nonpolar solvent such as hexane is accompanied by the appearance of a broad structureless emission band of the exciplex at higher wavelengths than anthracene. When the solvent polarity increases, the exciplex band is red shifted. The intensity of this band decreases as a result of the competition between de-excitation and dissociation of the exciplex.

Exciplexes can be considered in some cases as intermediate species in electron transfer from a donor to an acceptor (see Section 14.2.3).

14.3.5
Photoinduced Proton Transfer

Only reactions in aqueous solutions are considered here. Thus, an acid or a base undergoing excited-state deprotonation or protonation, respectively, will always be in close contact with water molecules acting as either a proton acceptor or a proton donor. Therefore, these excited-state reactions will not be diffusion controlled.

Excitation may trigger a photoinduced proton transfer when acids and bases are stronger in the excited state than in the ground state. For instance, the acidic character of a proton-donor group (e.g., OH substituent of an aromatic ring) can be enhanced upon excitation so that the p*K** of this group in the excited state is much lower than the p*K* in the ground state (Table 14.4). In the same manner, the p*K** of a proton-acceptor group (e.g.,

Tab. 14.4 Examples of p*K* and p*K** values. (Adapted from Valeur (2002).)

Reaction		Compound	pK	pK*
Excited-state deprotonation	$ArOH \xrightarrow{-H^+} ArO^-$	Phenol	10.6	3.6
		2-Naphthol	9.3	2.8
		2-Naphthol-6-sulfonate	9.12	1.66
		2-Naphthol-6, 8-disulfonate	9.3	<1
		8-Hydroxypyrene-1,3,6-trisulfonate (pyranine)	7.2	1.3
	$ArNH_2 \xrightarrow{-H^+} ArNH^-$	2-Naphthylamine	7.1	12.2
Excited-state protonation	$ArCO_2^- \xrightarrow{+H^+} Ar\ CO_2H$	Anthracene-9-carboxylate	3.7	6.9
	$ArN \xrightarrow{+H^+} ArNH^+$	acridine	5.5	1.6
		6-methoxyquinoline	5.2	11.8

heterocyclic nitrogen atom) in the excited state can be much higher than in the ground state (pK) (Table 14.4).

14.3.5.1 Equations for Excited-State Deprotonation

The general equations are given only in the most extensively studied case where the excited-state process is proton ejection (p$K^* \ll$ pK); the proton donor is thus an acid, AH*, and the proton acceptor is a water molecule. Assuming that there is no geminate proton recombination, the processes are presented in Scheme 14.5, where τ_0 and τ_0' are the excited-state lifetimes of the acidic (AH*) and basic (A^{-*}) forms, respectively, and k_1 and k_{-1} are the rate constants for deprotonation and reprotonation, respectively. k_1 is a pseudo-first-order rate constant, whereas k_{-1} is a second-order rate constant. The excited-state equilibrium constant is $K^* = k_1/k_{-1}$.

The probability that the back reaction can take place during the excited-state lifetime of A^{-*} is of utmost importance. The rate of this reaction is pH dependent because the process is diffusion controlled ($k_{-1} \approx 5 \times 10^{10}$ l mol^{-1} s^{-1}). If pH ≤ 2, $k_{-1}[\mathrm{H_3O^+}] > \approx 5 \times 10^8$ s^{-1}: the back reaction must then be taken into account. The reciprocal of this value is indeed of the order of the excited-state lifetime of most organic bases.

According to Scheme 14.5, the differential equations expressing the time evolution of the concentration of the species are

$$\frac{d[\mathrm{AH}^*]}{dt} = -\left(k_1 + \frac{1}{\tau_0}\right)[\mathrm{AH}^*] + k_{-1}[\mathrm{A}^{-*}][\mathrm{H_3O^+}] \qquad (14.67)$$

$$\frac{d[\mathrm{A}^{-*}]}{dt} = k_1\,[\mathrm{AH}^*] - \left(k_{-1}\,[\mathrm{H_3O^+}] + \frac{1}{\tau_0'}\right)[\mathrm{A}^{-*}] \qquad (14.68)$$

When AH is selectively excited by a δ-pulse of light, the responses of the fluorescence intensities, under the following initial conditions (at $t = 0$), $[\mathrm{AH}^*] = [\mathrm{AH}^*]_0$ and $[\mathrm{A}^{-*}]_0 = 0$, are

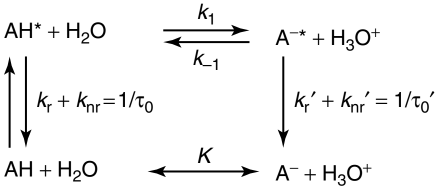
$$i_{\mathrm{AH}^*}(t) = k_r\,[\mathrm{AH}^*] = \frac{k_r\,[\mathrm{AH}^*]_0}{\beta_1 - \beta_2} \times \left[(X - \beta_2)e^{-\beta_1 t} + (\beta_1 - X)e^{-\beta_2 t}\right] \qquad (14.69)$$

$$i_{\mathrm{A}^{-*}} = k_r'\,[\mathrm{A}^{-*}] = \frac{k_r'\,k_1\,[\mathrm{AH}^*]_0}{\beta_1 - \beta_2} \times \left[e^{-\beta_2 t} - e^{-\beta_1 t}\right] \qquad (14.70)$$

where k_r and k_r' are the radiative rate constants of AH* and A^{-*}, respectively, and β_1 and β_2 are given by

$$\beta_{2,1} = \frac{1}{2}\left\{X + Y \pm \left[(Y - X)^2 + 4k_1k_{-1}[\mathrm{H_3O^+}]\right]^{1/2}\right\} \qquad (14.71)$$

where $X = k_1 + 1/\tau_0$ and $Y = k_{-1}[\mathrm{H_3O^+}] + 1/\tau_0'$.



Scheme 14.5 Excited-state deprotonation of an acid AH.

Under continuous illumination, the steady-state intensities can be easily calculated by integration of Eqs (14.69) and (14.70):

$$I_{\mathrm{AH}^*} = C\Phi_0 \frac{1 + k_{-1}\tau_0'[\mathrm{H_3O^+}]}{1 + k_1\tau_0 + k_{-1}\tau_0'[\mathrm{H_3O^+}]} \tag{14.72}$$

$$I_{\mathrm{A}^{-*}} = C\Phi_0{}' \frac{k_1\tau_0}{1 + k_1\tau_0 + k_{-1}\tau_0'[\mathrm{H_3O^+}]} \tag{14.73}$$

where Φ_0 and $\Phi_0{}'$ are the fluorescence quantum yields of AH and A^-, respectively, in the absence of excited-state reaction ($\Phi_0 = k_r\ \tau_0$; $\Phi_0{}' = k_r{}'\ \tau_0{}'$). C is a multiplication factor that is introduced to take into account the experimental conditions (total concentration, choice of excitation and emission wavelengths, bandpasses for absorption and emission intensity of the incident light, and sensitivity of the instrument).

Under conditions where the back reaction cannot take place during the excited-state lifetime ($k_{-1} = 0$), β_1 and β_2 become equal to X and Y, respectively, and Eqs (14.69) and (14.70) are reduced to

$$i_{\mathrm{AH}^*}(t) = [\mathrm{AH}^*]_0\ k_r\ e^{-Xt} \tag{14.74}$$

$$i_{\mathrm{A}^{-*}}(t) = \frac{k_r'\ k_1[\mathrm{AH}^*]_0}{X - Y}\left[e^{-Yt} - e^{-Xt}\right] \tag{14.75}$$

where $X = k_1 + 1/\tau_0$ and $Y = 1/\tau_0{}'$. Therefore, $i_{\mathrm{AH}^*}(t)$ becomes a single exponential and $i_{\mathrm{A}^{-*}}(t)$ is still a difference of two exponentials with a rise time $(1/X)$ (equal to the decay time of AH^*) and a decay time $(1/Y)$ (equal to the lifetime of the basic form).

The steady-state intensities reduce to

$$I_{\mathrm{AH}^*} = C\Phi_0 \frac{1}{1 + k_1\tau_0} \tag{14.76}$$

$$I_{\mathrm{A}^{-*}} = C\Phi_0' \frac{k_1\tau_0}{1 + k_1\tau_0} \tag{14.77}$$

14.3.5.2 Determination of the Excited-State p*K**

Estimation by Means of the Förster Cycle pK^* can be theoretically predicted by means of the Förster cycle associated with spectroscopic measurements. Details on the theory can be found in Valeur (2002) p. 103. Only the final equation is given here at 298 K:

$$\mathrm{p}K^* - \mathrm{p}K = 2.1 \times 10^{-3}(\overline{\nu}_{\mathrm{A}^-} - \overline{\nu}_{\mathrm{AH}}) \tag{14.78}$$

where $\overline{\nu}_{\mathrm{AH}}$ and $\overline{\nu}_{\mathrm{A}^-}$ are the wavenumbers (in cm^{-1}) corresponding to the 0–0 transitions of AH and A^-. The determination of $\overline{\nu}_{\mathrm{AH}}$ and $\overline{\nu}_{\mathrm{A}^-}$ is the major cause of inaccuracy in the estimation of pK^*. They are usually estimated by means of the average between the wavenumbers corresponding to the maxima of absorption and emission :

$$\nu_0 = \frac{\overline{\nu}_{\mathrm{abs}}^{\max} + \overline{\nu}_{\mathrm{em}}^{\max}}{2} \tag{14.79}$$

However, the best approximation is to use the intersection point of the mutually normalized absorption and emission spectra (as it was the practice in Förster's laboratory). In the case of large Stokes shift, it may be difficult to determine an intersection point and it is then preferable to take the average of the wavenumbers corresponding to half-heights of the absorption and emission bands, which is a better approximation than the average of the wavenumbers corresponding to the maxima.

The simplicity of the Förster cycle method explains why it has been extensively used. One of the important features of this cycle is the possibility to use it even in the case where the equilibrium is not established within the excited-state lifetime.

Steady-State Measurements The value of the excited-state pK^* can be determined by fluorometric titration but only when the equilibrium is established in the excited state. Rewriting Eqs (14.72) and (14.73) as $I_{\mathrm{AH}^*} = C\Phi$ and $I_{\mathrm{A}^{-*}} = C\Phi'$, it is easy to obtain the following relation:

$$\frac{\Phi/\Phi_0}{\Phi'/\Phi'_0} = \frac{1}{k_1\tau_0} + \frac{k_{-1}\tau'_0}{k_1\tau_0}[\mathrm{H_3O^+}] \tag{14.80}$$

Consequently, if the excited-state lifetimes τ_0 and τ_0' are known, the plot of $(\Phi/\Phi_0)/(\Phi'/\Phi_0')$ versus $[\mathrm{H_30^+}]$ yields the rate constants k_1 and k_{-1}. The ratio k_1/k_{-1} yields K^*.

Time-Resolved Experiments The most reliable method for the determination of k_1 and k_{-1} is based on time-resolved experiments. They provide the values of the decay times from which the rate constants k_1 and k_{-1} are determined by means of Eqs (14.69) and (14.70).

14.3.5.3 pH Dependence of Absorption and Emission Spectra

The absorption and fluorescence spectra are pH dependent when the acido-basic properties are not the same in the ground and excited states. The discussion is restricted again to the most important case of photoinduced proton ejection ($\mathrm{p}K^* \ll \mathrm{p}K$). Let us recall that for pH values less than approximately 2, the back reaction occurs. Moreover, distinction should be made according to the value of $\mathrm{p}K^*$.

1. If $\mathrm{p}K^*$ is greater than approximately 2, a plateau is observed for the relative fluorescence quantum yield of the acidic form and the basic form between $\mathrm{p}K^*$ and $\mathrm{p}K$ (Figure 14.5) because of the absence of diffusional recombination (see Eqs (14.75) and (14.76)). A typical example is 2-naphthol ($\mathrm{p}K = 9.3$, $\mathrm{p}K^* = 2.8$).
2. If $\mathrm{p}K^*$ is smaller than approximately 2, the acid is very strong in the excited-state and, in general, k_1 is much larger than the reciprocal of the excited-state lifetime so that the fluorescence of the acidic form is not observed at $\mathrm{pH} > \mathrm{p}K^* + 2$ but only for lower pH values (Figure 14.5). This is the case of pyranine ($\mathrm{p}K = 7.7$, $\mathrm{p}K^* = 1.3$).

14.3.6
Excitation Energy Transfer

Distinction between radiative and nonradiative transfer is of major importance (Valeur, 2002 Chapter 4, p. 110, and Chapter. 9); Andrews and Demidov, 1999. In radiative transfer a photon emitted by a molecule D is absorbed by a molecule A (or D). This process is observed when the average distance between D and A (or D) is larger than the wavelength. It does not require any interaction between the partners, but it depends on the spectral overlap and on the concentration. In contrast, nonradiative transfer occurs without emission of photons at distances lower than the wavelength and results from short- or long-range interactions between molecules. For instance, nonradiative transfer by dipole–dipole interaction is possible at distances up to 8–10 nm. Consequently, such a transfer provides a tool for determining distances of a few nanometers between chromophores. It should be

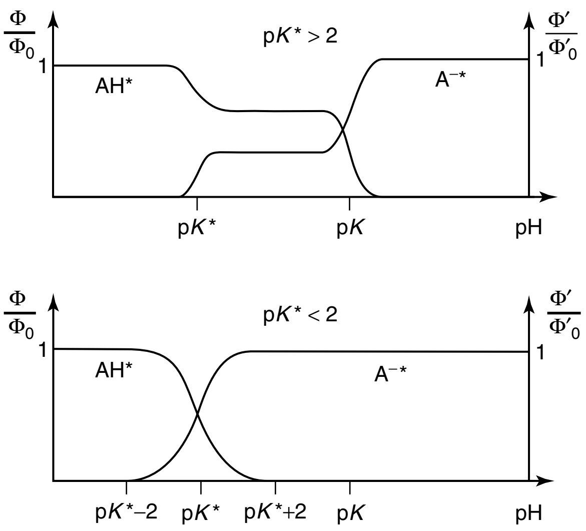


Fig. 14.5 Variations in relative quantum yields of the basic and acidic forms as a function of pH. (Reproduced with permission from Valeur (2002). Copyright Wiley-VCH Verlag GmbH & Co. KGaA.)

noted that the transfer of excitation energy plays a major role in photosynthetic systems.

Nonradiative transfer of excitation energy requires some interaction between a donor molecule and an acceptor molecule, and it can occur if the emission spectrum of the donor overlaps the absorption spectrum of the acceptor so that several vibronic transitions in the donor have practically the same energy as the corresponding transitions in the acceptor. Such transitions are coupled, that is, are in *resonance* and, hence, the term *resonance energy transfer* (*RET*). *Fluorescence resonance energy transfer* (FRET) is often employed, but this expression is not correct because it is not the fluorescence that is transferred but the electronic energy of the donor. Therefore, it is recommended to use either EET (*excitation energy transfer* or *electronic energy transfer*) or RET.

Different interaction mechanisms are involved in RET. The interactions may be Coulombic and/or due to intermolecular orbital overlap. The Coulombic interactions consist of long-range dipole–dipole interactions (Förster's mechanism) and short-range multipolar interactions. The interactions due to intermolecular orbital overlap, which include electron exchange (Dexter's mechanism) and charge resonance interactions, are only short range.

14.4
Applications of Molecular Fluorescence

14.4.1
Historical Introduction

Fluorescence has long been used as an analytical tool for the determination of the concentrations of neutral or ionic species (Valeur, 2007). In his famous book *History of Luminescence*, Harvey (1957) reports that Victor Pierre, who was a professor in Prague and later in Vienna, published a paper in 1862 in which he described the investigation of solutions of single fluorescent compounds and mixtures. He noted that bands of fluorescent spectra were characteristic of a particular substance. He also noted the effect of solvent and acidity or alkalinity. G. G. Stokes – who invented the term fluorescence – had certainly the same idea in mind. In fact, one of the topics of his famous Burnett lectures was " Fluorescence – Its use as a means of discrimination." However, no specific example was given in the text.

The term *fluorescence analysis* was employed for the first time in the paper by Göppelsröder (1868): the drastic enhancement of fluorescence intensity accompanying the complexation of morin (a hydroxyflavone derivative) with aluminum provides a straightforward way to detect this metal.

The use of fluorescent tracers in hydrology is also an old application of fluorescence. Uranin (the disodium salt of fluorescein) was used for the first time in 1877 as a tracer for monitoring the flow of Danube. On all maps, it is shown that the Danube springs in the Black Forest and, after many hundreds of kilometers, flows into the Black Sea. However, because of big sink (swallow holes) in the bed of Danube, it was demonstrated, thanks to the fluorescent tracer, that only a small part of the water from Danube spring arrives at the Black Sea. Most of it flows into the North Sea. Fluorescence tracing is now currently used in hydrology, especially to simulate pollutions.

Numerous applications of fluorescence were developed at the beginning of the twentieth century and reported in several books Radley and Grant (1933); Dake and De Ment (1941); Pringsheim and Vogel (1943). For instance, in the second part of the book of Radley and Grant (1933), the list of applications of fluorescence analysis is impressive: agriculture, bacteriology, botany, ceramics, slags and cements, drugs, foods and food products, fuels, inorganic chemistry, leather and tanning, legal work, medical and biological sciences, minerals and gems, museum work, organic chemistry, paints and varnishes, paper and cellulose and its derivatives, the rubber industry, textiles, and waters and sewage. Pringsheim and Vogel (1943) also gave various examples of application including fluorescent carpets and ceilings in theaters or fluorescent ballets.

The applications of fluorescence that are currently used are now presented.

14.4.2
Estimation of Local Physical Parameters

Physical parameters, such as viscosity, temperature, and pressure, can be locally estimated by means of fluorescent probes, that is, fluorescent compounds whose emissive properties are affected by one of these parameters.

14.4.2.1 Viscosity

Basic Concepts It is important to first recall that viscosity is a macroscopic parameter that loses its physical meaning at a molecular scale (Valeur, 2002 Chapter 8; Valeur, 1993). The term *microviscosity* must be used but with caution. The term *fluidity* is appropriate to characterize, in a very general way, the effects of viscous drag and cohesion of the probed microenvironment (polymers, micelles, gels, lipid bilayers of vesicles or biological membranes, etc.).

In all fluorescence techniques permitting evaluation of the fluidity of a microenvironment by means of a fluorescent probe, the underlying physical quantity is a diffusion coefficient expressing the viscous drag of the surrounding molecules (Figure 14.6).

Let us first recall that the diffusion coefficients for translational and rotational diffusions are, respectively,

$$D_t = \frac{kT}{6\pi\eta r} \tag{14.81}$$

$$D_r = \frac{kT}{8\pi\eta r^3} = \frac{kT}{6\eta V} \tag{14.82}$$

where k is the Boltzman constant, T is the absolute temperature, η is the viscosity, r is the hydrodynamic radius of the sphere, and V is its hydrodynamic volume.

The use of these equations to estimate the viscosity η of an unknown environment from the experimental value of the diffusion constant is questionable. In fact, these equations are valid only for a rigid sphere being large compared to the molecular dimensions, moving in a homogeneous newtonian fluid and obeying the Stokes hydrodynamic law. Many other relations have been proposed, but it should be pointed out that *there is no satisfactory relationship between diffusion and bulk viscosity for probes*. The main reason is that the size of probes is comparable to that of the surrounding molecules forming the microenvironment to be probed. Another difficulty arises in the case of organized assemblies such as micellar systems, biological membranes, and so on, because the microenvironment is not isotropic.

In other words, *viscosity is a macroscopic parameter and any attempt to get absolute values of the viscosity of a medium from measurements using a fluorescent probe is hopeless*.

It is always observed that the diffusion of molecular probes is more rapid than predicted by the theory. Therefore, the "slip" boundary condition is often introduced, and sometimes a mixture of "stick" and "slip" boundary conditions is assumed. Relation (14.82) can then be

rewritten as

$$D_r = \frac{kT}{6\eta Vsg} \tag{14.83}$$

where s is the coupling factor ($s = 1$ for "stick" and $s < 1$ for "slip" boundary conditions) and g is the shape factor. In the case of charged molecules, an additional friction force should be introduced as a result of the induced polarization of the surrounding solvent molecules.

A faster diffusion than predicted can be explained by the fact that a solute molecule moves according to two diffusional processes: a viscous process with displacement of solvent molecules (*Stokes diffusion*) and a process associated with migration into holes of the solvent (*free volume diffusion*). The importance of free volume should be emphasized at a molecular level. An empirical relation between viscosity and free volume was proposed by Doolittle:

$$\eta = \eta_0 \exp\left(\frac{V_0}{V_\mathrm{f}}\right) \tag{14.84}$$

where η_0 is a constant and V_0 and V_f are the Van der Waals volume and the free volume of the solvent, respectively.

The choice of the method for probing fluidity depends on the system to be investigated. The use of intermolecular quenching and intermolecular excimer formation is not recommended for probing fluidity of microheterogeneous media because of possible perturbation of the translational diffusion process. The methods of molecular rotors and intramolecular excimer formation are convenient and rapid, but the time-resolved fluorescence polarization technique provides much more detailed information, including an order parameter if the medium is anisotropic.

Use of Molecular Rotors A *molecular rotor* – as a fluorescent probe – is a molecule that undergoes internal rotation(s) resulting in viscosity-dependent changes of its emissive properties. They belong to the family of diphenylmethane dyes (e.g., auramine O), triphenylmethanes dyes (e.g., crystal violet), and twisted intramolecular charge transfer (TICT) compounds (e.g., *p*-dimethylaminobenzonitrile (DMABN)). Examples of molecular rotors of practical interest are given in Figure 14.7.

In solvents of medium and high viscosity, an empirical relation based on free volume considerations has been proposed to account for the viscosity dependence of the fluorescence quantum yield:

$$\Phi_F \cong b\left(\frac{\eta}{T}\right)^x \tag{14.85}$$

where x is a constant for a particular probe.

In polymers above the glass transition temperature, the fluorescence quantum yields were, in fact, found to be a power function of the bulk viscosity with values of the exponent x lower than 1 (e.g., for *p*-*N*,*N*-dimethylaminobenzylidenemalononitrile, $x = 0.69$ in glycerol and 0.43 in dimethylphtalate).

Molecular rotors are a powerful tool to study changes in free volume of polymers as a function of molecular weight, stereoregularity, crosslinking, polymer chain relaxation, and flexibility. Monitoring of polymerization reactions is possible in this way (Loufty, 1986).

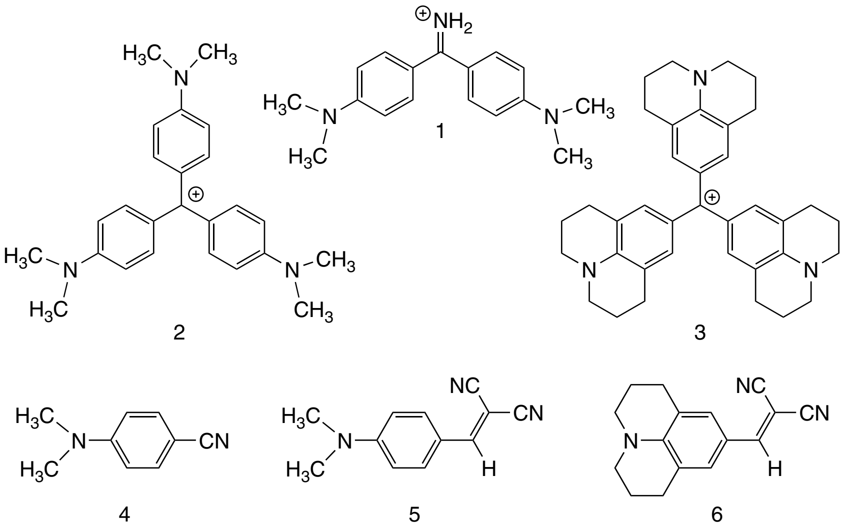

Fig. 14.7 Examples of molecular rotors. 1, auramine O; 2, crystal violet; 4, *p*-*N*,*N*-dimethylaminobenzonitrile (DMABN); 5, *p*-N,N-dimethylaminobenzylidenemalononitrile; 6, julolidinebenzylidenemalononitrile.

Method Based on Intramolecular Excimer Formation Bifluorophoric molecules consisting of two identical fluorophores linked by a short flexible chain may form an excimer. Examples of such bifluorophores currently used in investigations of fluidity are given in Figure 14.8.

The efficiency of intramolecular excimer formation does not depend on the concentration of fluorophores so that Eq. (14.66) should be rewritten by replacing $k_1[\mathrm{M}]$ by k_1:

$$\frac{I_E}{I_M} = \frac{k'_r}{k_r}\tau_E\, k_1 \tag{14.86}$$

It should be noted that when effects of temperature on fluidity are investigated, difficulties may arise from the possible temperature dependence of the excimer lifetime. It is then recommended to perform time-resolved fluorescence experiments.

As in the case of molecular rotors, free volume effects are important, but the free volume fraction measured by intramolecular excimers is smaller than for molecular rotors. The volume swept out during the conformational change required for excimer formation is in fact larger, and consequently these probes do not respond in frozen media or polymers below the glass transition temperature.

The following empirical relation is currently used for the rate constant for excimer formation:

$$k_1 = \alpha\, \eta^{-x} \tag{14.87}$$

It is important to note that in addition to viscosity, the response of a probe depends on several parameters: chemical nature of the solvent, length of the chain, temperature, and oxygen quenching (Viriot *et al.*, 1983).

Intramolecular excimers have been used for probing bulk polymers, micelles, vesicles, and biological membranes (Viriot *et al.*, 1983; Bokobza and Monnerie, 1986; Bokobza, 1990;

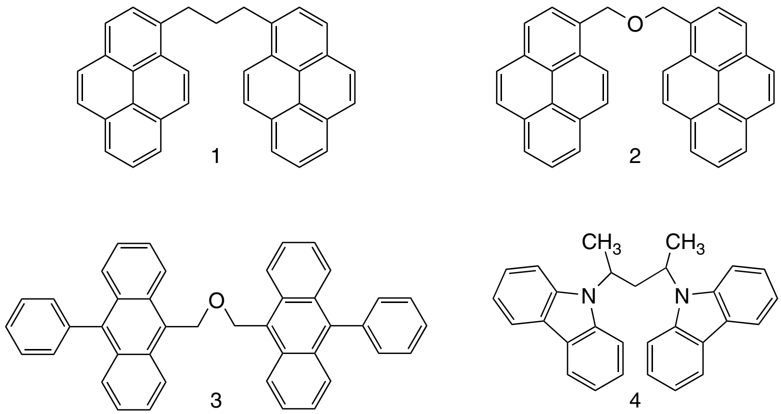

Fig. 14.8 Examples of bifluorophores forming excimers for the study of fluidity. 1, α,ω-di-(1-pyrenyl)propane; 2, α,ω-di-(1-pyrenyl)methylether; 3, 10,10′-diphenyl-*bis*-9-anthrylmethyloxide (DIPHANT); 4, meso-2,4-di(*N*-carbazolyl)pentane.

Georgescauld *et al.*, 1980; Vauhkonen *et al.*, 1990; Zachariasse and Kozankiewicz, and Kühnle, 1983).

Fluorescence Polarization Method The preferred orientation of fluorescent probes resulting from photoselection at time zero is gradually affected as a function of time by the rotational Brownian motions if the medium is fluid enough to permit rotation of the probes during the excited-state lifetime. This causes a depolarization of fluorescence, from which information can be obtained on the molecular motions that depend on the size and the shape of molecules and on the fluidity of their microenvironment.

A molecule undergoes isotropic rotation if it is spherical, but this is also the case of a rodlike molecule whose directions of its absorption and emission transition moments coincide with the long molecular axis (e.g., diphenylhexatriene): the rotations can be considered as isotropic because any rotation about this long axis has no effect on the emission anisotropy.

For isotropic motions in an isotropic medium, the values of the instantaneous and steady-state emission anisotropies are given by

$$r(t) = r_0 \exp(-6D_r t) \tag{14.88}$$

$$\frac{1}{\bar{r}} = \frac{1}{r_0}(1 + 6D_r \tau) \tag{14.89}$$

which allows one to determine the diffusion constant D_r. In principle, a value of the viscosity η could be calculated from the Stokes–Einstein relation (Eq. (14.82) or (14.83)) provided that the hydrodynamic volume V of the probe is known. It should be again emphasized that any "microviscosity" value calculated in this way would be questionable and thus useless. Nevertheless, the changes in D_r upon an external perturbation (e.g., temperature, pressure, additive, etc.) reflect well the changes in fluidity of a medium.

In ordered systems such as lipid bilayers and liquid crystals, the rotational motions of a probe are hindered and the emission anisotropy does not decay to zero but to a steady value r_∞. Equations (14.88) and (14.89) are thus no longer valid. For isotropic rotations (rodlike probe), the emission anisotropy can often be written in the following approximated form:

$$r(t) = (r_0 - r_\infty)\ \exp\left(-\frac{t}{\tau_c}\right) + r_\infty \tag{14.90}$$

where τ_c is the effective relaxation time of $r(t)$, that is, the time with which the initially photoselected distribution of orientations approaches the stationary distribution.

Time-resolved emission anisotropy experiments yield τ_c, r_0, and r_∞. The data can be processed according to the *wobble-in-cone model* (Kinosita, Kawato and Ikegami, 1977; Lipari and Szabo, 1980) in which the rotations of a rodlike probe (with the direction of its absorption and emission transition moments coinciding with the long molecular axis) are restricted within a cone. The rotational motions are described by the rotational diffusion coefficient D_w around an axis perpendicular to the long molecular axis and an order parameter (half angle of the cone θ_c) reflecting the degree of orientational constraint due to the surrounding paraffinic chains. θ_c can be determined from the ratio r_∞/r_0, and D_W from τ_c and θ_c.

The rotations of the probe are thus describe by (i) the wobbling diffusion constant D_w reflecting the fluidity of the medium, and more precisely the chain mobility and (ii) the order parameter θ_c, half angle of the cone, expressing the degree of orientational constraint.

More general theories have been developed (Van der Meer, Kooyman and Levine, 1982; Van der Meer *et al.*, 1984; Zannoni, Arcioni and Cavatorta, 1983; Fisz, 1985; Szabo, 1984; Pottel *et al.*, 1986).

14.4.2.2 **Temperature**

Fluorescent molecular thermometers are based on the temperature dependence of the photophysical properties of fluorescent compounds (fluorescence spectrum, fluorescence quantum yield, and excited-state lifetime) (Chandrasekharan and Kelly, 2004; Uchiyama, de Silva and Iwau, 2006). Temperature is indeed a key parameter of several photophysical processes: intersystem crossing (Section 14.2.1.3), delayed fluorescence (Section 14.2.1.3), and excimer or exciplex formation (Section 14.3.4).

The advantages of fluorescent molecular thermometers over contact temperature sensors are the following: absence of sensitivity to electromagnetic radiation, fast response, and spatial resolution from the nanoscale to the macroscale (temperature-sensitive paints).

The compounds whose fluorescence quantum yield is more or less strongly affected by temperature changes are either organic (e.g., perylene, acridine yellow, perylenedicarboximide, rhodamine B, pyronine B, pyronine Y) or organometallic (e.g., ruthenium or europium complexes : Ru(bpy), $\mathrm{Ru(phen)_3}$, Europium thenoyltrifluoroacetonate (EuTTA)).

For instance, the temperature dependence of the fluorescence quantum yield of a solution of rhodamine B has been exploited for spatial and temporal mapping of temperature within the microchannel networks of microfluidic devices. Changes in fluorescence intensity were used to determine intrachannel temperature variations with a precision of ±3 °C, a spatial resolution of 1 μm, and a temporal resolution of 33 milliseconds (Ross, Gaitan and Locascio, 2001). With the same aim, fluorescence lifetime imaging (FLIM) has been used to quantitatively image temperature distributions in three spatial dimensions within microchannels environments (Benninger *et al.*, 2006). The advantage of lifetime measurements is that, unlike fluorescence intensity, excited-state lifetime is independent of fluorophore concentration, fluctuations of the light source, and photobleaching effects.

Ratiometric measurements, that is the ratio of the fluorescence intensities at two observation wavelengths, offer the same advantage. This requires a change in the shape of the fluorescence spectrum as a function of temperature. This is, for instance, the case of exciplex formation with perylene and *N*-allyl-*N*-methylaniline (NA), leading to the appearance of a broad fluorescence band centered at 550 nm (Chandrashekaran and Kelly, 2001):

$$\underset{\text{(blue fluorescence)}}{\text{Perylene}} + \text{NA} \rightleftarrows \underset{\text{(green fluorescence)}}{\text{Perylene-NA}}$$

A film consisting of perylene and NA encapsulated and anchored, respectively, in a soft elastic polystyrene matrix is a temperature sensor whose working range is 25–85 °C. Figure 14.9 shows the effect of temperature changes on the emission spectra.

An interesting application of fluorescent molecular thermometers concerns real-time polymer processing monitoring. Measurements by thermocouples and infrared imaging are not accurate in this case. Benzoxazolyl stilbene and

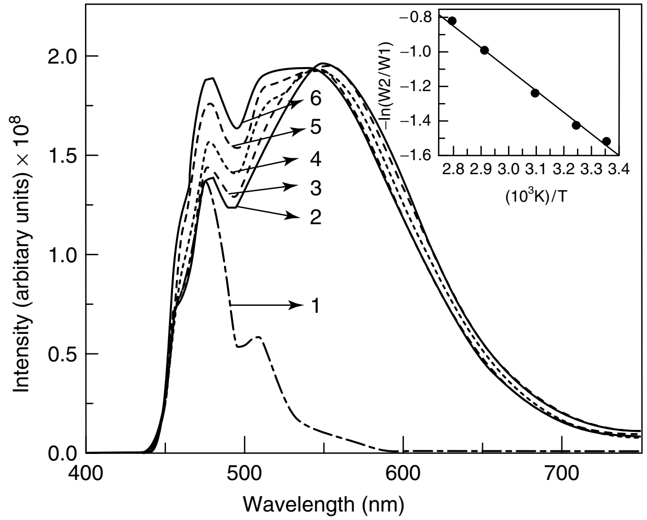

Fig. 14.9 Effect of temperature on the emission spectra of a polystyrene film composed of 0.017 wt % of perylene and 18.96 wt % of *N*-allyl-*N*-methylaniline : (2) 298 K; (3) 304 K; (4) 323 K; (5) 343 K; (6) 358 K; (1) film of perylene alone at 298 K. Excitation wavelength: 386 nm. (Reproduced with permission from Chandrashekaran and Kelly (2001). Copyright 2001 American Chemical Society.)

perylene were chosen because of their compatibility with polymer matrices and their high thermal stability. Morever, the relative intensities of the vibronic bands are temperature dependent, which allow ratiometric measurements. Plots of the intensity ratio versus temperature are linear with a slope of 0.09–0.2% per degree. Temperatures as high as 300 °C can be measured (Bur, Wangel and Roth, 2002).

Optical thermometers based on the thermally activated delayed fluorescence have been proposed. Acridine yellow dissolved in a rigid saccharide glass exhibits a temperature-dependent ratio of fluorescence to phosphorescence intensity, but the effect is weak (Fister, Rank and Harris, 1995). A much stronger effect has been observed with fullerene C_{70}, which shows very intense delayed fluorescence (see Section 14.2.1.3). For C_{70} dispersed in a polymer matrix (poly(*ter*-butyl methacrylate)), the working range extends from −80 to 140 °C (Baleizao *et al.*, 2007). Figure 14.10 shows the increase in intensity of red fluorescence. The working range is even wider when monitoring the lifetime of the delayed fluorescence.

Tab. 14.5 Temperature ranges of temperature-sensitive paints.

Compound	**Temperature range (°C)**
Perylene	0–100
Perylenedicarboximide	50–100
Rhodamine B	0–80
Pyronine B	50–100
Pyronine Y	0–100
Ruthenium complex Ru(bpy)	0–90
Europium complex EuTTA[a]	−20 to 80

[a] Europium theonyltrifluoroacetonate.

Surface temperature mapping can be obtained by using paints containing temperature-sensitive fluorescent compounds (Liu et and Sullivan, 2005). Table 14.5 gives examples of such compounds together with the temperature ranges. In aerodynamics, temperature-sensitive paints are employed in conjunction with pressure-sensitive paints (PSPs) (see the following section) (Liu *et al.*, 1997). Both paints are also used in advanced turbomachinery applications

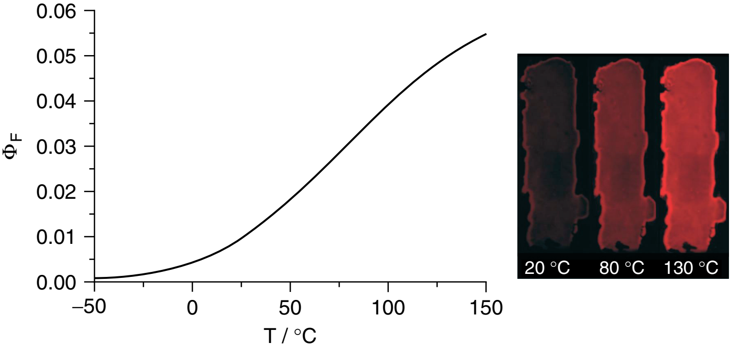

Fig. 14.10 Fluorescence quantum yield versus temperature for C_{70} dispersed in a polymer matrix (poly(*ter*-butyl methacrylate)) and color picture at three temperatures. (Reproduced with permission from Baleizao *et al.* (2007). Copyright Wiley-VCH Verlag GmbH & Co. KGaA.)

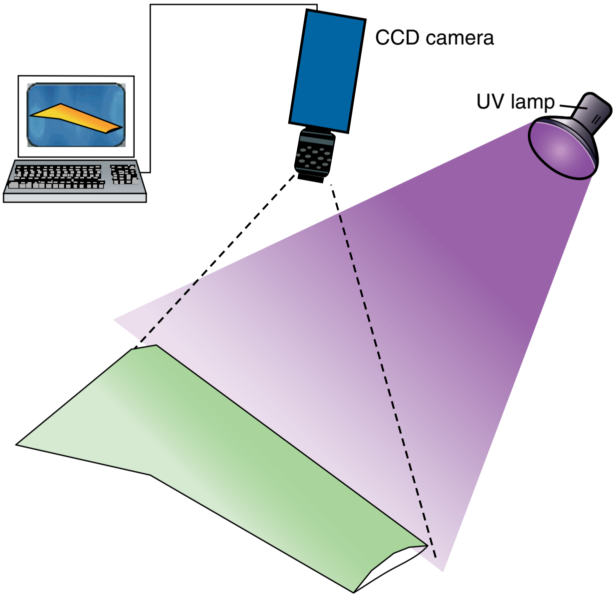

Fig. 14.11 Experimental set-up for temperature and pressure surface mapping using temperature- and pressure-sensitive paints.

(Navarra *et al.*, 2001). Figure 14.11 shows the experimental set-up.

At a microscopic scale, *fluorescence microthermography* is a powerful technique for generating high-resolution thermal maps of integrated circuits and for hot-spot localization in electrical failure analysis (Kolodner and Tyson, 1982; Herzum *et al.*, 1998). The europium complex EuTTA is well suited for these measurements. The lateral resolution is 0.5 μm and the thermal resolution is in the millikelvin range. This technique is thus superior to other routine thermography methods (liquid crystal thermography, infrared thermography, or laser thermoreflectance).

14.4.2.3 **Pressure**

An interesting application of fluorescence quenching is the use of fluorescent paints sensitive to air pressure, with the aim at studying the aerodynamism of aircraft or car models in wind tunnels. Such PSPs sprayed on a model provide a surface pressure mapping, that is, the instantaneous two-dimensional pressure distribution on the surface. They are more convenient and cheaper than the numerous pressure sensors that would be required.

PSPs are oxygen sensitive: they contain fluorophores whose fluorescence is quenched by oxygen (Figure 14.12). Therefore, the larger the air pressure, the larger the partial pressure of oxygen, and the higher the efficiency of quenching of the fluorophores that are embedded in a transparent polymer. Fluorophores should have a long excited-state lifetime: pyrene derivatives and ruthenium complexes are thus suitable for this application.

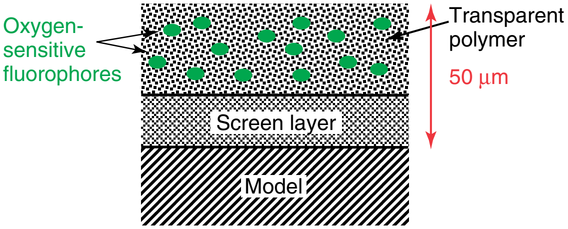

Fig. 14.12 Pressure-sensitive paint on a model.

The Stern–Volmer equation that holds for collisional quenching of fluorescence (Eq. (14.33)) must be rewritten in the following alternative form:

$$\frac{I_0}{I} = A + B\frac{P}{P_0} = \frac{\tau_0}{\tau} \tag{14.91}$$

where I, τ, and P are the fluorescence intensity, the excited-state lifetime, and the pressure, respectively. The subscripts 0 refer to the atmospheric pressure. In some cases, excited-states lifetimes are measured instead of fluorescence intensities.

Since the 1980s the PSP technique has been mainly used in aeronautics for transonic and supersonic flow studies, and it is now currently used in industrial wind tunnels (Liu *et al.*, 1997).

Surface pressure mapping is more difficult to obtain in the case of cars because the variations in pressure are smaller at low speed. Figure 14.13 shows an investigation carried out in ONERA (Engler *et al.*, 2002). The PSP is made of pyrene with gadolinium oxysulfide as reference dye (insensitive to oxygen) that permits correction for the nonhomogeneous distribution of illumination. The pressure map accurately reveals the variations in pressure at the roof/rear window junction.

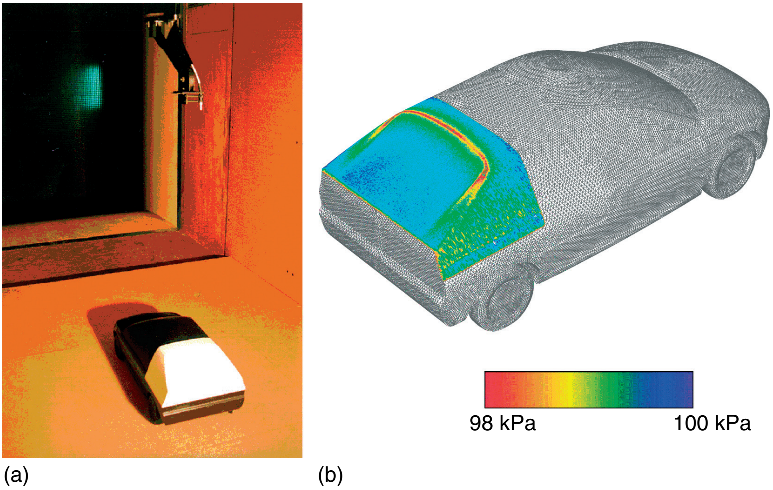

Fig. 14.13 Model of a Peugeot 206 car in a wind tunnel (a) and pressure map (b). (Courtesy of M.C. Merienne, ONERA, France.)

14.4.3
Chemical Sensing

Fluorescence is extensively used for chemical sensing in many fields: analytical chemistry, biology, biotechnology, clinical diagnostics, toxicology, environment, forensics, and chemical oceanography (Lakowicz, 1994; de Silva and Tecilla, 2005; Narayanaswamy and Wolfbeis, 2004). The success of fluorescence can be explained by the distinct advantages that this technique offers in terms of sensitivity, selectivity, response time, local observation under microscope, and remote detection by means of optical fibers.

In principle, a *fluorescent sensor* is the complete optical sensing device containing the light source, the analyte-responsive (supra)molecular moiety properly immobilized (e.g., in plastified polymers, sol–gel matrices, etc.), the optical system (involving an optical fiber or not), and the light detector (photomultiplier or photodiode) connected to appropriate electronics for displaying the signal. When considering only the fluorescent analyte-responsive (supra)molecular moiety, the term *fluorescent molecular sensor* should be used.

14.4.3.1 Fluorescent Molecular Sensors

The design of a fluorescent molecular sensor that is selective of a given analyte is actually a work of molecular engineering that involves many disciplinary fields: photophysics, photochemistry, analytical chemistry, physical chemistry, coordination chemistry, and supramolecular chemistry (Valeur, 2002 Chapter 10; Desvergne and Czarnik, 1997).

The fluorophores that are implied in fluorescent molecular sensors are numerous: naphthalene, anthracene, pyrene, aminonaphthalimide, diaminonaphthylsulfonyl, coumarins, fluorescein, eosin, rhodamines, benzidine, alizarin, seminaphthofluorescein, oligo- and polyphenylenes, porphyrins, ruthenium complexes, and so on.

Much progress has been made in sensitivity and selectivity toward a given analyte. The main targets are the following:

- cations: H_3O^+ (pH), alkali, alkaline-earth, transition, and post-transition;
- anions: fluoride, chloride, carboxylates, phosphates, (adenosine triphosphate) ATP, nitrates, and so on; and
- molecules: hydrocarbons, aminoacids, sugars, urea, ammonia, amines, alcohols, O_2, CO_2, H_2O_2, and so on.

Three classes of fluorescent molecular sensors are to be distinguished (Figure 14.14):

- Class 1: fluorophores that undergo quenching upon collision with an analyte (e.g., O_2, Cl^-).
- Class 2: fluorophores that can reversibly bind an analyte. If the analyte is a proton, the term *fluorescent pH indicator* is often employed. If the analyte is an ion, the term *fluorescent chelating agent* is appropriate. Fluorescence can be either quenched or enhanced upon binding. In the case of enhancement, the compound is said to be *fluorogenic* (e.g., 8-hydroxyquinoline (oxine)).
- Class 3: fluorophores linked, via a spacer or not, to a receptor that ensures appropriate affinity and selectivity toward a given analyte. The changes in fluorescence characteristics of the fluorophore upon interaction with the bound analyte result from the perturbation by the latter of photoinduced processes such as electron transfer, charge transfer, energy transfer, and

excimer or exciplex formation or disappearance. The design of such sensors is relevant to the fields of supramolecular chemistry and photophysics. In the case of ion recognition, the receptor is called *ionophore*, and the whole molecular sensor is called *fluoroionophore*.

Fluorescent pH Indicators Fluorescent pH indicators offer a much better sensitivity than the classical dyes, such as phenolphthalein, thymol blue, and so on, based on color change. They are thus widely used in analytical chemistry, bioanalytical chemistry, cellular biology (for measuring intracellular pH), and medicine (for monitoring pH and pCO_2 in blood; pCO_2 is determined via the bicarbonate couple). In microscopy, fluorescent pH indicators provide spatial information on pH. Moreover, remote sensing of pH is possible by means of fiber-optic chemical sensors.

A fluorescent indicator AH can undergo deprotonation according to the following equilibrium:

$$\mathrm{AH} + \mathrm{H_2O} \rightleftarrows \mathrm{A^-} + \mathrm{H_3O^+} \qquad (14.92)$$

The true value of the acidity constant (that depends only on temperature) must be written with activities:

$$K_\mathrm{A} = \frac{a_{\mathrm{A^-}} a_{\mathrm{H_3O^+}}}{a_\mathrm{AH}} \qquad (14.93)$$

Using the definition of pH

$$\mathrm{pH} = -\log a_{\mathrm{H_3O^+}} \qquad (14.94)$$

Equation (14.93) can be rewritten in the following form:

$$\mathrm{pH} = \mathrm{p}K_\mathrm{A} + \log \frac{a_{\mathrm{A^-}}}{a_\mathrm{AH}} \qquad (14.95)$$

$$\mathrm{pH} = \mathrm{p}K_\mathrm{A} + \log \frac{f_{\mathrm{A^-}}}{f_\mathrm{AH}} + \log \frac{[\mathrm{A^-}]}{[\mathrm{AH}]} \qquad (14.96)$$

where $f_{\mathrm{A^-}}$ and f_AB are the activity coefficients relative to molarities.

In very dilute aqueous solutions, the activity coefficients are close to 1 (reference state: solute at infinite dilution), and Eq. (14.96) reduces to the well-known Henderson–Hasselbach equation:

$$\mathrm{pH} = \mathrm{p}K_\mathrm{A} + \log \frac{[\mathrm{A^-}]}{[\mathrm{AH}]} \qquad (14.97)$$

Otherwise, $\mathrm{p}K_A$ should be replaced by an apparent pK:

$$\mathrm{p}K_\mathrm{app} = \mathrm{p}K_\mathrm{A} + \log \frac{f_{\mathrm{A^-}}}{f_\mathrm{AH}} \qquad (14.98)$$

Hence,

$$\mathrm{pH} = \mathrm{p}K_\mathrm{app} + \log \frac{[\mathrm{A^-}]}{[\mathrm{AH}]} \qquad (14.99)$$

$\mathrm{p}K_\mathrm{app}$ depends on ionic strength, specific interactions between the indicator and the medium, and structural changes of the medium. For instance, $\mathrm{p}K_\mathrm{app}$ differs significantly from $\mathrm{p}K_A$ at the interface of micelles or lipid bilayers.

For fluorometric titrations, the following relation can be used (Valeur, 2002 p. 338):

$$\mathrm{pH} = \mathrm{p}K_\mathrm{app} + \log \frac{I - I_\mathrm{A}}{I_\mathrm{B} - I} \qquad (14.100)$$

where I is the fluorescence intensity at a given wavelength, and I_A and I_B are the fluorescence intensities measured at the same wavelength when the indicator is only in the acidic form or only in the basic form, respectively.

It is recommended, whenever possible, to carry out ratiometric measurements, that is, to determine the ratio of the fluorescence intensities measured at two excitation wavelengths or two emission wavelengths. The ratiometric measurements are indeed preferable because the ratio of the fluorescence intensities at two wavelengths is independent of the total concentration of the dye, photobleaching, fluctuations of the source intensity, and sensitivity of the instrument. Examples of fluorescent

Tab. 14.6 Examples of fluorescent pH indicators allowing ratiometric measurements. (From Valeur (2002).)

Fluorophore	pK_A	Type of measurement
4-MU	7.8	excitation ratio 365/335 nm
Pyranine	7.2	excitation ratio 450/400 nm
fluorescein	2.2, 4.4, 6.4	excitation ratio 490/435 nm
BCECF	7.0	excitation ratio 505/439 nm
SNAFL dyes	7.0–7.8	excitation ratio 490/540 nm or emission ratio 540/630 nm
SNARF dyes	7.0–7.8	emission ratio 580/630 nm
CNF	7.5	excitation ratio 600/510 nm or emission ratio 550/670 nm

4-MU, 4-methylumbelliferone; BCECF, 2′,7′-bis(carboxyethyl)-5(or 6)-carboxyfluorescein; SNAFL, semi-naphthofluoresceins; SNARF, semi-naphthorhodafluors; CNF, carboxynaphthofluorescein.

pH indicators allowing ratiometric measurements are given in Table 14.6.

For ratiometric measurements, the following equation may be used to fit the calibration curve (Valeur, 2002 p. 338):

$$\mathrm{pH} = \mathrm{p}K_{\mathrm{app}} + \log \frac{R - R_{\mathrm{A}}}{R_{\mathrm{B}} - R} + \log \frac{I_{\mathrm{A}}(\lambda_2)}{I_{\mathrm{B}}(\lambda_2)} \tag{14.101}$$

where R is the ratio $I(\lambda_1)/I(\lambda_2)$ of the fluorescence intensities at two excitation wavelengths (or two emission wavelengths) λ_1 and λ_2. R_A and R_B are the values of R when only the acidic form or the basic form is present, respectively. $I_A(\lambda_2)/I_B(\lambda_2)$ is the ratio of the fluorescence intensity of the acidic form alone to the intensity of the basic form alone at the wavelength λ_2 chosen for the denominator of R. It should be emphasized that R, R_A, and R_B are very sensitive to the wavelengths chosen and also to instrumental settings.

According to the preceding relations, the usual working range is about 2 pH units around pK_A. However, the working range is broader when the indicator possesses more that one pK_A (e.g., fluorescein).

Fluorescent Molecular Sensors of Cations

Detecting cations is of great interest in many fields: chemistry, biology, clinical biochemistry, and environment (de Silva *et al.*, 1997; Valeur, 1994; Valeur and Leray, 2000). Sodium, potassium, magnesium, and calcium are involved in biological processes such as transmission of nerve impulse, muscle contraction, regulation of cell activity, and so on. Zinc is an essential component of many enzymes (e.g., in carbonic anhydrase and zinc finger proteins); it plays a major role in enzyme regulation, gene expression, neurotransmission, and so on. In medicine, monitoring of metal ions (e.g., Na^+, K^+, Mg^{2+}, Ca^{2+}, Li^+) in blood and urines is of major importance for diagnosis. In medicine, it is necessary to control the lithium level in the serum for patients under treatment for maniac depression and potassium in the case of high blood pressure. In environment, early detection of toxic metal ions such as mercury, lead, and cadmium is of interest. In chemical oceanography, it has been demonstrated that some nutrients required for the survival of microorganisms in sea water contain zinc, iron, and manganese as enzyme cofactors.

In the design of a fluorescent molecular sensor of cations, called *fluoroionophore*, much attention is to be paid to the characteristics of the ionophore moiety and to the expected changes in fluorescence characteristics of the fluorophore moiety upon binding.

The ionophore can be a chelator, an open-chain structure (podand), a macrocycle (coronand, e.g., crown ether), a macrobicycle (cryptand), a calixarene derivative, and so on. The characteristics of the ionophore, that is, the ligand topology and the number and nature of the complexing heteroatoms or groups, should match the characteristics of the cation, that is, ionic diameter, charge density, coordination number, and intrinsic nature (e.g., hardness of metal cations, nature and structure of organic cations, etc.) according to the general principles of supramolecular chemistry.

The ionophore may be linked to the fluorophore via a spacer, but in many cases some atoms or groups participating in the complexation belong to the fluorophore. Therefore, the selectivity of binding often results from the whole structure involving both signaling and recognition moieties.

The changes in emissive properties of the fluorophore upon cation binding are due to the cation control of photoinduced electron transfer (PET), photoinduced charge transfer (PCT), excimer formation or disappearance, and excitation energy transfer. The discussion is restricted to the most popular PET and PCT sensors.

In a PET sensor (Bissell *et al.*, 1992), excitation of the fluorophore induces the promotion of an electron of the HOMO to the LUMO, which enables PET from the HOMO of the donor (cation-free receptor) to that of the fluorophore, causing fluorescence quenching of the latter (see Section 14.3.3). Upon cation binding, the redox potential of the donor is raised so that the relevant HOMO becomes lower in energy than that of the fluorophore. Therefore, PET is not possible any more and fluorescence quenching is suppressed. Examples of PET sensors are given in Figure 14.15.

In a PCT sensor (Valeur and Leray, 2001), the fluorophore contains an electron-donating group (often an amino group) conjugated to an electron-withdrawing group and thus undergoes intramolecular charge transfer from the donor to the acceptor upon excitation by light. The consequent change in dipole moment results in a Stokes shift that depends on the microenvironment of the fluorophore. Therefore,

- when a cation is in close interaction with the donor moiety (such as an amino group), it reduces the efficiency of intramolecular charge transfer and the fluorescence spectrum is blue-shifted.
- when a cation is in close interaction with the acceptor moiety, it enhances the efficiency of intramolecular charge transfer and the fluorescence spectrum is red shifted.

In addition to these spectral shifts, changes in quantum yields and lifetimes are often observed. All the photophysical effects are obviously dependent on the charge and the size of the cation, and selectivity of these effects is expected.

Fluorescent Molecular Sensors of Anions Anions play key roles in chemical and biological processes. Many anions act as nucleophiles, bases, redox agents, and phase transfer catalysts. Most of enzymes bind anions as either substrates or cofactors. The chloride ion is of special interest because it is crucial in several phases of human biology and in disease regulation. Moreover, it is of great interest to detect anionic pollutants such as nitrates and phosphates in ground water.

Anion molecular sensors are either based on collisional quenching (in general, they exhibit a poor selectivity) or based on recognition by an anion receptor linked to a fluorophore (fluoroionophore), which is described later.

Many fluorescent molecular sensors for halide ions (except F$^-$) are based on collisional quenching of a dye. In particular, the determination of chloride anions in living cells is achieved according to this principle. Examples of halide ion sensors are given in Figure 14.17. The drawback of these molecular sensors is their lack of selectivity. Moreover, the absence of spectral change precludes ratiometric measurements. However, dual-wavelength Cl$^-$ sensors have been designed.

Anion sensors containing an anion receptor have a much better selectivity. Sensors of phosphate and pyrophosphate groups have attracted much attention because of their biological relevance. Figure 14.18 shows some examples.

14.4.3.2 **Microfabricated Analysis Systems**

Miniaturization of sensing devices has been the object of considerable effort. Microfabricated systems indeed offer many advantages that are of particular

interest in the case of biological samples: high speed, online monitoring, and low consumption of samples and reagents. The development of lab-on-chips with, in particular, the DNA gene chips is impressive. Microfabricated analysis systems, called *micro-total analysis systems* (μ-*TASs*), are based on microfluidic technology using microchipchannels, microreactors, valves, and pumps (Reyes *et al.*, 2002; Auroux *et al.*, 2002). Among the detection methods employed in these systems, fluorescence deserves attention. The applications are mainly relevant to life sciences: clinical diagnostics, immunoassays, DNA separation and analysis, sequencing, and so on.

A nice example is the very sophisticated microfluidic device developped by Richard Mathies and coworkers (University of California at Berkeley) for the detection of aminoacids in future missions on Mars (Skelley *et al.*, 2005) (Figure 14.19). It is based on capillary electrophoresis and the use of fluorescamine as a fluorescence marker for aminoacids. The first step of the analysis is sublimation of amines and aminoacids onto an aluminum disk spin-coated with fluorescamine. Successful tests were carried out in Atacama desert in Chile, which can be considered as the best Mars analog site because it is one of the most arid regions in the world. Sensitivity ranges from micromolar to 0.1 nM, corresponding to part-per-trillion sensitivity.

14.4.4
Tracers in Biology

Molecular fluorescence is widely used in biology for cellular imaging using (confocal) fluorescence microscopy. pH imaging and ion imaging (calcium, magnesium, zinc, chloride, etc.) are possible by using appropriate fluorescent pH indicators or fluorescent molecular sensors for ions (see Section 14.4.2). With the aim at tracing cellular components during biological processes, fluorescent species are used to visualize these components.

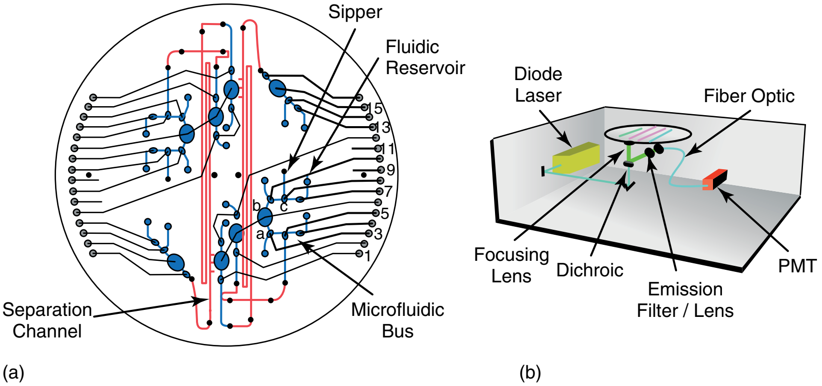

Fig. 14.19 Microdevice for amino acid biomarker detection and analysis on Mars. (a) Top view of the microdevice showing registration of the capillary electrophoresis channel (red), pneumatic manifold (black), and fluidic bus wafers (blue). (b) Schematic of the instrument showing confocal excitation and detection optics. (Reproduced with permission from Skelley *et al.* (2005), Copyright 2005 National Academy of Sciences, USA.)

In contrast to fluorescent probes, they should be insensitive to their microenvironment as much as possible. The four classes of fluorescent tracers in biology are organic fluorophores, fluorescent antibodies, fluorescent proteins, and semiconductor nanocrystals. The first two classes are well known and are not described here, whereas the use of fluorescent proteins and semiconductor nanocrystals is more recent and deserves particular attention.

14.4.4.1 Fluorescent Proteins

Fluorescent proteins become more and more popular as tracers in biology (Zimmer, 2002; Lippincott-Schwartz and Patterson, 2003). The first of them is green fluorescent protein (GFP) from *Aequora Vitoria,* a bioluminescent jelly fish. The green fluorescence is due to a partially cyclic tripeptide (serine, tyrosine, and glycine) in an α-helix. A fusion between a cloned gene and GFP can be created using standard techniques, which leads to a chimera that can be expressed in a cell. Thus, GFP acts as a fluorescent label of a protein of interest whose localization or activity is not affected. It is thus possible to visualize dynamic cellular events and to monitor protein localization.

Spectral variants of GFP emitting in the blue-cyan and the yellowish green have been generated, but the wavelength of the emission maximum is not greater than approximately 530 nm. However, corals (Anthozoa) can provide fluorescent proteins emitting in the red, such as DsRed.

The simultaneous use of several colors is thus possible. A beautiful example of multicolor imaging is shown in Figure 14.20.

At a larger scale, fluorescent proteins also offer an outstanding tool for imaging muscle fibers in vivo, so that one can see the effect of new therapies for muscle diseases.

At an even larger scale, a whole animal can be rendered fluorescent if all cells express the gene of GFP. This has been applied to rabbits, mice, rats, pigs, and silkworms. The interest is

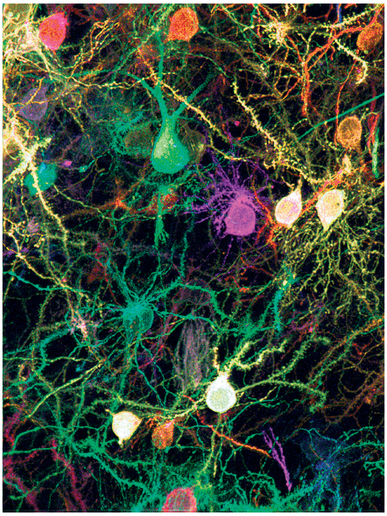

Fig. 14.20 Multicolor imaging of mossy fibers in the cerebellum of a transgenic mouse. This image taken by confocal microscopy shows mossy fibers in one folium of a young adult transgenic mouse. Spectral variants of GFP are expressed in a combinatorial way following genetic recombination mediated by cre-recombinase. The various colors are produced by the particular subset of fluorescent proteins expressed in each axon and their individual concentrations. In this animal, at least 12 distinct spectral fingerprints in different cells can be discerned. (Courtesy of J. Lichtman, Harvard University.)

that GFP makes it possible to follow the fate of cells in embryos, in normal organs, and in tumors, without requiring destruction of the cells. A transgenic fluorescent rabbit generated in the French *Institut National de la Recherche Agronomique* (INRA) appears green under UV illumination, even the eyes show green fluorescence. A bioartist, Eduardo Kac, from the Chicago University wished to breed these rabbits to be used as exotic pets, but this proposition was rejected by the French researchers.

In 2003, a company located in Texas put in the market a genetically modified aquarium fish having the capacity to be red fluorescent under UV illumination. This announcement was followed by protests coming from both activists and the scientific community. Indeed, this event raises several unanswered questions. Are these fish a threat for environment? Are they suffering from their transgene and from UV illumination? Is it ethical to use genetic engineering to generate this particular kind of pets? (Knight, 2003)

14.4.4.2 **Semiconductor Nanocrystals**

The fluorescence of semiconductor nanocrystals is not strictly relevant to molecular fluorescence, but their growing interest deserves attention here. The emissive properties of these nanocrystals, also called *quantum dots*, are due to quantum confinement. The emission wavelength ranges from the UV to the infrared depending on the nature of the semiconductor and the size of the nanocrystal. For quantum dots made of cadmium selenide with a protective coating of zinc sulfide, the emission wavelength ranges from the blue (diameter of 2 nm) to the red (diameter of 7 nm).

Quantum dots offer distinct advantages for tracing owing to their specific characteristics:

- broad absorption spectrum allowing a common excitation wavelength for nanocrystals having different emission wavelengths;
- narrow emission spectrum (gaussian) : 12–15 nm;
- fluorescence quantum yield greater than 50%;
- excellent photostability;
- coatable for water solubility and biocompatibility.

It should be emphasized that the photostability of quantum dots is much better than that of organic dyes, and they are much brighter in tissue. It is thus possible to monitor the trajectories of nanocrystals for 20 minutes, instead of 5 seconds with an antibody coupled to an organic fluorophore such as Cy3 (Dahan *et al.*, 2003).

Quantum dots have also been successfully used for in vivo cancer targeting and imaging (Gao *et al.*, 2004). Applications to encoding are also of great interest. For this purpose, nanocrystals are embedded in various proportions into polymer microspheres with millions of possible combinations. These microspheres can then be attached to DNA sequences, peptides, and so on, and are thus useful for high throughput screening (genomics, proteomics, and drug screening).

14.4.5
Clinical Diagnostics

14.4.5.1 **Critical Care Analysis**

The Osmetech/Roche OSPI critical care analyzer can measure up to eight critical care analytes in whole blood (Tusa and He, 2005): pH, CO_2/Hb, O_2, Na^+, K^+, Ca^{2+}, or Cl^-. Six appropriate fluorescent molecular sensors are embedded in separate disks on a disposable cartridge. It takes not more than 2 minutes to get the result from 120 μl of whole blood. The list of the analytes, the normal range, the pathological range, and the relevant molecular sensors are reported in Table 14.7. Pyranine is used as a fluorescent pH indicator. CO_2 is determined in the following way: a membrane blocks the passage of H_3O^+ and other ions into the sensor but allows CO_2 through, where it forms carbonic acid, increasing the local concentration of H_3O^+ that is determined by pyranine. Cation recognition is achieved by fluoroionophores consisting of the naphthalimide fluorophore linked to an azacrown for Na^+, a cryptand for K^+, and a chelating moiety for Ca^{2+} (Figure 14.21). The dissociation constants are consistent with the pathological ranges.

14.4.5.2 Angiography

Angiography is a good example of application of fluorescence for in vivo diagnostics. Fluorescent tracers are used to visualize the blood vessels of the retina in order to detect anomalies: lesions, aneurisms, and occlusions resulting from specific eye diseases.

A fluorescent dye (fluorescein or indocyanine green) is injected into a vein in the arm of the patient. The dye is conveyed by the circulatory system and reaches the retina vessels.

Figure 14.22 shows an angiogram observed after injection of fluorescein: the existence of bright points leads to the diagnostic of an early diabetic retinopathy showing microaneurisms.

Indocyanine green provides information on deeper tissues, as compared to fluorescein. Because it absorbs near 800 nm and emits in the near infrared, it can reveal deeper vessels called *choroidal vessels*. In the case of an aged-related macular degeneration, leaky vessels, that is, choroidal neovascularization, can be visualized, while the angiogram with fluorescein also shows fluid leakage for the same patient.

14.4.5.3 Bladder Tumor Detection

The measurement of relative fluorescence intensities of tryptophan and NADH by endoscopy permits early detection of bladder tumors in situ. Light pulses from an excimer laser (308 nm) are conveyed by a catheter containing several optical fibers. Fluorescence is

Tab. 14.7 Fluorescent sensors for critical care analytes. (Adapted from Tusa and He (2005).)

	Normal range	Pathological range	Fluorescent sensor
pH	7.35–7.45	6.7–7.7	pyranine
$P(CO_2)$ (torr)	30–45	10–200	pyranine
$P(O_2)$ (torr)	70–100	20–600	Oxygen-sensitive dye
Na^+ (mM)	135–145	100–180	Naphthalimide dye – azacrown[a]
K^+ (mM)	3–5	1–10	Naphthalimide dye – cryptand[a]
Ca^{2+} (mM)	1.0–1.4	0.3–2.5	Naphthalimide dye – chelator[a]

[a] See Figure 14.21.

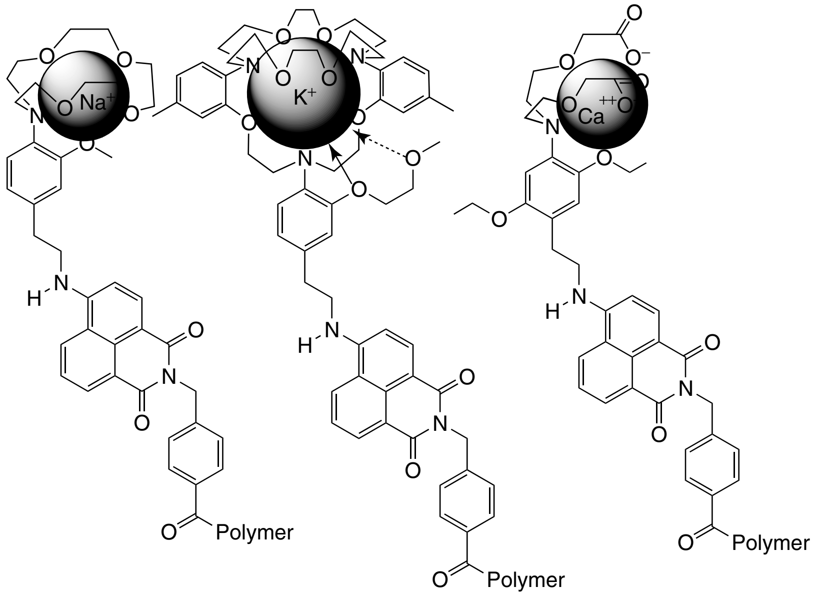

Fig. 14.21 Fluoroionophores for the selective detection of Na^+, K^+, and Ca^{2+}. (Reproduced from Tusa and He (2005) by permission of the Royal Society of Chemistry.)

collected by other fibers and analyzed by a monochromator and a photomultiplier (Figure 14.23) (Avrillier *et al.*, 1997). The fluorescence spectra are different according to the state of the tissue. For tumors and carcinoma in situ (CIS), the ratio of the fluorescence intensities at 360 and 440 nm is statistically greater than 2. This test is reliable and can be run during routine visit.

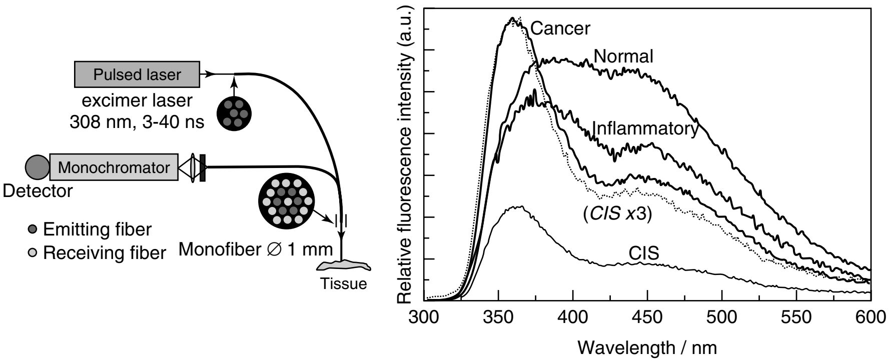

Fig. 14.23 Experimental set-up for the detection of bladder tumors. Fluorescence spectra of normal, inflammatory and cancerous tissues upon excitation at 308 nm (CIS, carcinoma in situ). (Adapted from Avrillier *et al.* (1997).)

14.4.6
Miscellaneous

14.4.6.1 Fluorescence LIDAR

LIDAR is the acronym of light detection and ranging (which is a transposition of RADAR for radiowave detection and ranging). LIDAR is a useful tool for atmospheric monitoring and, in particular, for the detection of SO_2 and NO_2 in atmosphere. This technique that is based on back-scattering and absorption of species can be extended to fluorescence detection by using appropriate emission filters. The applications concern the status of vegetation, the estimation of plankton in sea water, and imaging of the façades of historical monuments.

A Nd:YAG laser is often used for these applications: it provides excitation pulses of about 10 nanoseconds duration at 532 and 355 nm, thanks to frequency doubling and tripling, respectively.

Vegetation It is of great interest to monitor the chemical activities and the status of trees and forests. Early detection and mapping of damaged vegetation as a consequence of pollution can also be made. Remote detection of chlorophyll by a LIDAR is possible. Upon excitation at 532 nm, the chlorophyll concentration can be estimated as a function of time by taking the ratio of the intensity of the images at 740 and 685 nm (Saito *et al.*, 2000). The test is validated by the comparison of the average intensity ratio and the amount of chlorophyll determined by chromatography. The average intensity ratio follows the chlorophyll concentration that increases in summer and decreases in autumn.

Sea Water The detection of fluorescence from chlorophyll in phytoplankton and from phycoerythrin-containing plankton (e.g., cyanobacteria) (both excited at 532 nm) is possible from aircrafts or ships, thanks to a LIDAR. The biomass can thus be estimated. In addition, the fluorescence of dissolved organic substances can be detected upon excitation at 355 nm. NASA has developed an airborne oceanographic LIDAR and a shipboard laser fluorometer to achieve such evaluations.

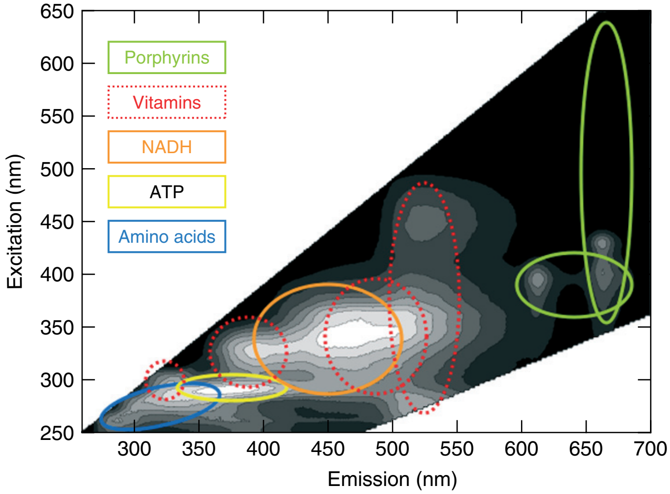

Fig. 14.24 Two-dimensional excitation–emission patterns of typical food-relevant fluorophores. (Reproduced with permission from Christensen *et al.* (2006). Copyright 2006 American Chemical Society.)

Façades of Historical Monuments Svanberg and coworkers have developed a system for imaging the laser-induced fluorescence from the façades of historical monuments (Weibring *et al.*, 2001). The aim is the visualization of areas of biodeterogen (lichens, green algae) and the identification of different stone types with natural surface aging or crust and pollution deposited layers. Façade status assesment is thus obtained in view of restauration planning.

The LIDAR system is placed in a truck at a distance of about 60 m from the façade. A 355-nm pulsed laser beam is swept over the façade row by row. The spectrally resolved fluorescence signals are recorded on each point.

14.4.6.2 Food Science

Food systems (meat, fish, dairy products, oils, cereals, beer, fruits, vegetables, etc.) contain several fluorescent substances such as proteins, vitamins, secondary metabolites, pigments, toxins, and flavoring compounds. The intrinsic fluorescence from intact food can thus provide valuable information on the quality of food products, their authenticity, and the effect of processing and aging. The emitted fluorescence is quite complex because of the presence of several intrinsic fluorophores. Moreover, the fluorescence signals are affected by phenomena such as Rayleigh and Raman scattering, inner filter effects, self-quenching, and so on. The complex signals can be decomposed from a series of two-dimensional excitation–emission patterns into the pure constituent signals using multiway chemometrics (Christensen *et al.*, 2006). Figure 14.24 shows the spectral properties of selected food-relevant fluorophores.

14.4.6.3 Forensics

On a crime scene, the visualization of fingerprints by means of powders is well known. The fluorescent powders are the most efficient.

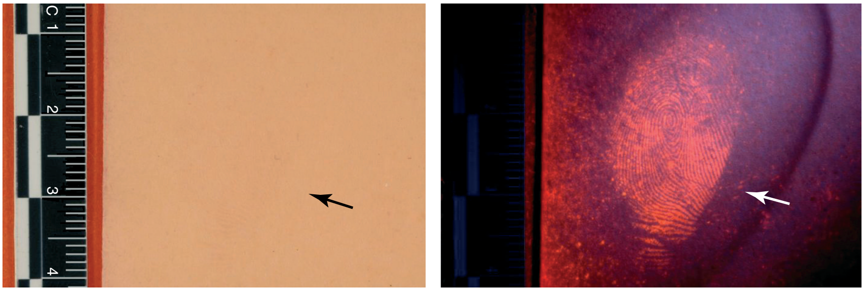

Fig. 14.25 Fingerprint on a piece of paper revealed by fluorescence after treatment with diaza-9-fluorenone. (Courtesy of the Identité judiciaire de la Préfecture de police de Paris.)

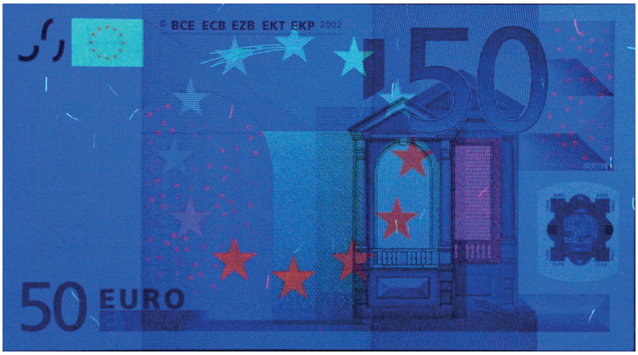

Fig. 14.26 A bill of 50 Euros shows specific color under UV illumination (photograph by the author.)

Fingerprints on papers are more difficult to detect, especially when they are old. In this case, the procedure is to soak the paper in a solution of diaza-9-fluorenone (that reacts with aminoacids present in the sweat deposited by the fingers), and to dry it. Observation under UV illumination can reveal the fluorescent fingerprints provided that the blue fluorescence of paper due to whitening agents is rejected by means of an appropriate filter (Figure 14.25).

14.4.6.4 **Counterfeit Detection**

In many situations, the luminescent pattern serves as a security check for documents, especially for bills. Various luminescent compounds either organic or inorganic are employed. For example, the Euros bills show different colors (e.g., stars, Europe map, etc.) under UV illumination (Figure 14.26). Small fluorescent fibers can also be seen.

The use of semiconductor nanocrystals (Section 14.4.4.4) to counterfeit detection is to be expected in the near future (bank notes, ID cards, badges, etc.).

Fluorescence is also a means to detect counterfeited art works: paintings, ceramics, glassware, sculptures, ivories, old marbles, and so on. In fact, fluorescence depends on ageing. Moreover, traces of restoration, overpainting, falsified signatures, and so on can also be easily detected.

In conclusion, fluorescence is a very powerful tool in both fundamental and applied research. The technological and industrial applications are numerous in variegated fields. The success of fluorescence as a tool of investigation of the structure and dynamics of matter or living systems arises from the high sensitivity of fluorometric techniques, the specificity of fluorescence characteristics due to the microenvironment of the emitting molecule, and the ability of the latter to provide spatial and temporal information. After a long history, no doubt that fluorescence still has a bright future.

15.1
Introduction

Resonance energy transfer[1] (RET) is a spectroscopic process whose relevance in all major areas of science is reflected both by the wide prevalence of the effect and through numerous technical applications. It is an optical near-field mechanism that effects the transportation of electronic excitation between physically distinct atomic or molecular components, based on transition dipole–dipole coupling. In this chapter, a comprehensive survey of the process is presented, beginning with an outline of the history and highlighting the early contributions of Perrin and Förster. This is followed by a review of the photophysics and then a discussion of some prominent applications of RET. Particular emphasis is given to techniques used in molecular biology, ranging from the "spectroscopic ruler" measurements of functional group separation to fluorescence lifetime microscopy. Finally, applications to synthetic polymers and chemical sensors are examined.

15.2
History of RET

15.2.1
The First Experiments

RET is a process by means of which the energy of an excited atom or molecule (usually called the *donor*, but known historically as the *sensitizer*) is transferred nonradiatively to an acceptor molecule ("activator"), through intermolecular dipole–dipole coupling. The origins of its discovery can be traced back to 1922, when the phenomenon of RET ("sensitized fluorescence") was first experimentally observed by Franck (1922); Cario (1922); Cario and Franck (1922) in the gas phase. This spectroscopic experiment involved illuminating a mixture of mercury and thallium vapors at a wavelength absorbed solely by the mercury; the resulting fluorescence spectra was proven to include frequencies that could only be emitted from thallium. Such energy transfer in vapors was at first assumed to be uniquely associated with interatomic collisions, but a discovery that transfer could occur at larger separations than the collision radii showed that this was not necessarily the case. Soon, RET was also being observed in solutions (Gaviola

---

[1] RET is also known as Förster – or fluorescence – resonance energy transfer (FRET), or electronic energy transfer (EET).

and Pringsheim, 1924), and over the following years in many other physical systems.

15.2.2
Early Developments of Theory

The first theoretical explanation of the phenomenon was proposed by the Nobel laureate Perrin (1927). He recognized that energy could be transferred from an excited molecule to its neighbors amongst closely spaced molecules through dipole interactions; he named this process as "transfert d'activation," and his paper on the subject became the earliest attempt to describe nonradiative (near-field) energy transfer. However, despite its initial success, Perrin's model incorrectly predicted that nonradiative energy transfer should be possible between dye molecules up to an intermolecular distance of 1000 Å, deriving from an inaccurate assumption that the molecules would act as Hertzian oscillators with exactly defined resonance frequencies. Five years later (Perrin, 1932), Perrin's son Francis developed a corresponding quantum mechanical theory of RET, based on the results of Kallman and London (1928). In this work, he recognized a "spreading of absorption and emission frequency" due to the interactions of the dye with the solvent, thus reducing the probability of energy transfer. As a result, efficient transfer was calculated to occur up to 150–250 Å, still approximately a factor of 3 greater than the experimentally observed. A detailed and readable survey of these early contributions of J. and F. Perrin can be found in a review by Berberan-Santos (2001).

15.2.3
Förster Theory

Extending the ideas of J. and F. Perrin, Förster developed the first essentially correct theoretical treatment of RET (Förster, 1946, 1948, 1959). Förster determined that energy transfer, through dipolar coupling between molecules, mostly depends on two important quantities: spectrum overlap and intermolecular distance. Following the observation that "the absorption and fluorescence spectra of similar molecules are far from completely overlapping," he found a means to quantify the spectral overlap integral. The dipole–dipole interaction was known to have an inverse proportionality on the cube of the molecular separation. Because the rate of energy transfer is proportional to the square of this coupling, it thus depends on the sixth power of the separation, that is, the famous R^{-6} distance-dependence law. Moreover, the acceptor distance at which this rate equates to that of spontaneous emission by the donor, now termed the *Förster radius* R_0, has been calculated to be between 10 and 100 Å, in agreement with experimental observations.

Much later, the distance dependence predicted by Förster was fully verified by fluorescence studies of donor–acceptor pairs at known separations (Latt, Cheung and Blout, 1965; Stryer and Haugland, 1967), leading to the suggested employment of RET as a "spectroscopic ruler" by Stryer and Haugland (1967); hence, a technique to measure the proximity relationships and conformational change in macromolecules was realized (see Section 15.3). With the advent of the laser, in the 1960s, the modern understanding of RET led to a raft of modern applications. An excellent in-depth review on the history of RET is given by Clegg (2006).

15.3
The Photophysics of RET

Resonance energy transfer is a mechanism that is now known to operate across a diverse and extensive range of physical systems, encompassing not only gases and dye solutions but also protein complexes, doped crystals, polymers, and so on. Nonetheless, at a fundamental level, it is possible to identify numerous common features in the underlying photophysics.

15.3.1
Primary Excitation Processes

To study the subject in detail, let us commence with the photoexcitation process that creates the conditions for RET to occur. When resonant ultraviolet or visible radiation impinges on any non-homogeneous dielectric material, the primary result of photon absorption is the population of electronic excited states in individual atomic, molecular, or other nanoscale centers – henceforth, to be grouped together under the generic term "chromophore." Typically, such absorption is immediately followed by a rapid but partial degradation of the acquired energy, the associated losses (largely due to vibrational dissipation) ultimately to be manifest in the form of heat. This effect owes its origin to the principle that the release of electronic energy by fluorescence generally occurs from the lowest vibrational level of the excited state. However, if any nearby chromophore has a suitably disposed electronic state, of a similar or slightly lower energy, that neighbor may acquire the major part of the electronic excitation

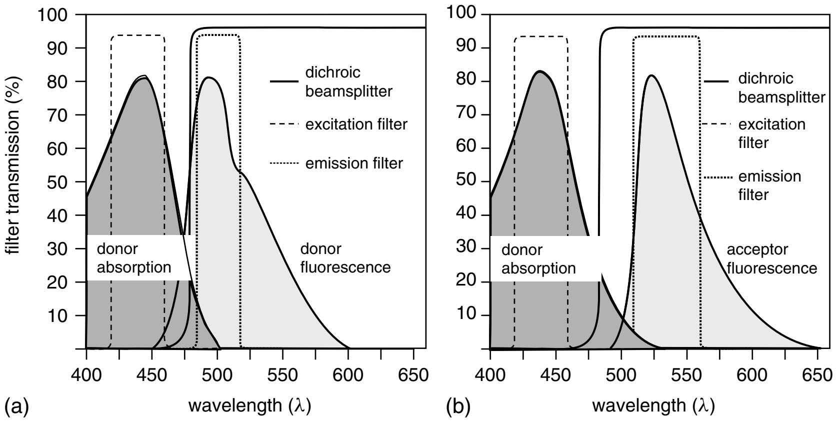

Fig. 15.1 Typical spectral discrimination between the fluorescence from donor and acceptor species (here notionally based on a cyan fluorescent protein donor and a yellow fluorescent protein acceptor): (a) the transmission characteristics of a short-wavelength filter ensure initial excitation of only the donor; a dichroic beam-splitter and another narrow emission filter ensure that only the (Stokes-shifted) fluorescence from the donor reaches a detector; (b) in the same system, a longer-wavelength emission filter ensures capture of only the acceptor fluorescence, following RET.

through RET – a process that takes place well before any further thermal degradation of the excited state energy occurs. The mechanism is most commonly studied through spectrometric differentiation of fluorescence emerging from the initially excited donor and from the acceptor species, as illustrated in Figure 15.1. As is shown in the following, the propensity for energy to be transferred between any two chromophores is severely restricted by distance, and if no suitable acceptor is within reach, the donor will generally shed its energy by fluorescence or local dissipation.

15.3.2
Coupling of Electronic Transitions

In systems where RET occurs, the donors and acceptors are usually fluorophores, that is, chromophores that have the capacity to exhibit fluorescence decay. Moreover, in RET, the transitions of donor decay and acceptor excitation are generally electric dipole-allowed – although other possibilities occasionally arise. Accordingly, the theory of energy transfer, for donor–acceptor displacements beyond the region of significant wavefunction overlap, is traditionally conceived in terms of an electrodynamical coupling between transition dipoles.

Consider the pairwise transfer of excitation between two chromophores D and A. In the context of this elementary mechanism, D is designated as the donor and A as the acceptor. Specifically, let it be assumed that prior excitation of the donor generates an electronically excited species D^*. Forward progress of the energy is then accompanied by donor decay to the ground electronic state. Acquiring the energy, D undergoes a transition from its ground to its excited state. The complete RET process is generally a singlet–singlet coupling mechanism[2], due to the constraints of spin conservation (although this does not apply to Dexter exchange, see below), and its entirety may be expressed by the following chemical equation:

$$ {}^1D^* + {}^1A \xrightarrow{\text{RET}} {}^1D + {}^1A^* \qquad (15.1) $$

The excited acceptor, A^*, subsequently decays either in a further transfer event or by another means such as fluorescence. Because the D^* and A^* excited states are real, with measurable lifetimes, the core process of energy transfer itself is fundamentally separable from the initial electronic excitation of D and the eventual decay of A; the latter processes do not, therefore, enter into the theory of the pair transfer.

15.3.3
Dissipation and Line-Broadening

To delve more deeply into the nature of the process, it needs to be recognized that Eq. (15.1) tells only part of the story, dealing as it does with only electronic excitations. In general, other dissipative processes are also engaged. In a solid, the linewidth of optical transitions manifests the influence of local electronic environments which, in the case of strong coupling, may lead to the production of phonon side-bands. Similar effects in solutions or disordered solids represent inhomogeneous interactions with a solvent or host, while the broad bands exhibited by chromophores in complex molecular systems signify extensively overlapped vibrational levels,

---

2) Triplet-triplet energy transfer is also allowed by the Förster mechanism.

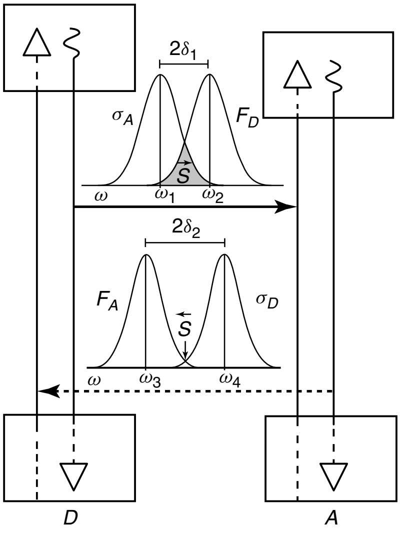

Fig. 15.2 Energetics and spectral overlap features (top) for energy transfer from *D* to *A* (and below, potentially backward transfer from *A* to *D*). For each chromophore, *F* denotes the fluorescence spectrum and σ the absorption. Wavy downward lines denote vibrational dissipation.

including those associated with skeletal modes of the superstructure. In each case, energy level broadening can allow pair transfer to occur at any point within the region of overlap between the donor emission and the acceptor absorption bands, as illustrated in Figure 15.2.

15.3.4
The Förster Equation

The Förster theory delivers an expression for the rate of pairwise energy transfer, w_F, valid for any donor–acceptor separation, R, that is substantially smaller than the wavelengths of visible radiation. For systems where the common host material for the donor and acceptor has refractive index n, at the optical frequency corresponding to the mean transferred energy, the Förster result is as follows (Demidov and Andrews, 2001):

$$w_F = \frac{9\kappa^2 c^4}{8\pi \tau_{D^*} n^4 R^6} \int F_D(\omega)\sigma_A(\omega)\frac{d\omega}{\omega^4} \tag{15.2}$$

In this expression, $F_D(\omega)$ denotes the normalized fluorescence spectrum of the donor, $\sigma_A(\omega)$ represents the linear absorption cross section of the acceptor, and ω is an optical frequency in radians per unit time; the specific form of the integral within which they appear is known as the *spectral overlap* – one of the key determinants of energy transfer efficiency (Andrews and Rodríguez, 2007). Also in Eq. (15.2), c is the speed of light and τ_{D^*} is the associated radiative decay lifetime in the absence of transfer. The latter is related to the measured fluorescence lifetime τ_{fl} through the fluorescence quantum yield $\eta = \tau_{\text{fl}}/\tau_{D^*}$, where τ_{fl}^{-1} is explicitly expressible as

$$\frac{1}{\tau_{\text{fl}}} = \frac{1}{\tau_{D^*}} + \frac{1}{\tau_{D^*}}\left(\frac{R_0}{R}\right)^6 \tag{15.3}$$

The last term on the right-hand side of Eq. (15.3) is expressed with reference to the Förster radius R_0 – the distance at which the rates of donor deactivation by RET and by spontaneous fluorescence become equal. As is evident from Figure 15.2, the propensity for forward transfer is usually significantly greater than that for backward transfer, due to a sizeable difference in the spectral overlaps for the two processes.

15.3.5
Orientation Dependence

The κ factor in Eq. (15.2) depends on the orientations of the donor and acceptor, both with respect to each other and with respect to their mutual displacement unit vector $\hat{\boldsymbol{R}}$, as follows:

$$\kappa = (\hat{\boldsymbol{\mu}}_D \cdot \hat{\boldsymbol{\mu}}_A) - 3(\hat{\boldsymbol{R}} \cdot \hat{\boldsymbol{\mu}}_D)(\hat{\boldsymbol{R}} \cdot \hat{\boldsymbol{\mu}}_A) \tag{15.4}$$

For each chromophore, $\hat{\boldsymbol{\mu}}$ designates a unit vector in the direction of the appropriate transition dipole moment. The possible values of κ^2, as featured in Eq. (15.2), lie in the range (0, 4). It is evident that in the case of fixed chromophore positions and orientations, the result delivered by Eq. (15.4) is a function of three independent angles, as shown and defined in Figure 15.3:

$$\kappa = \cos\theta_T - 3\cos\theta_D \cos\theta_A \tag{15.5}$$

Unfavorable orientations can thus reduce the rate of energy transfer to zero; other configurations, including many of those found in photobiological systems, optimize the transfer rate. The angular disposition of chromophores is therefore a very important facet of energy transfer. It is important to note that transfer is not *necessarily* precluded when the transition moments of the donor and acceptor lie in perpendicular directions – provided that neither is also disposed orthogonally to $\boldsymbol{R}(=R\hat{\boldsymbol{R}})$.

In any, at least partially, fluid or disordered system, the relative orientation of all donor–acceptor pairs may not be identical, and it is then the distributional average of κ^2 that determines the overall measured response. In the isotropic case (completely uncorrelated orientations), the κ^2 factor averages to $^2/_3$; departures from this value provide the quantitative signature of a degree of orientational correlation. In molecules of sufficiently high symmetry, it can also happen that either the donor or the acceptor transition moment is not unambiguously identifiable with a particular direction in the corresponding chromophore reference frame. Specifically, the electronic transition may then relate to a transition involving a degenerate state – as can occur with square planar complexes, for example (Galli *et al.*, 1993). Alternatively, the same

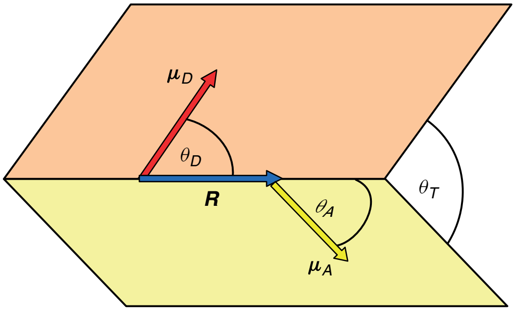

Fig. 15.3 Relative orientations and positions of the donor and acceptor and their transition moments: Here, angles θ_D and θ_A subtended by donor and acceptor transition moments ($\boldsymbol{\mu}_D$ and $\boldsymbol{\mu}_A$, respectively) against the inter-chromophore displacement vector, **R**; the symbol θ_T is the angle between the transition moments.

observational features might indicate rapid but orientationally confined motions. The considerable complication that each of these effects brings into the trigonometric analysis of RET has been extensively researched and reported by van der Meer (1999).

15.3.6
Förster Radius

In applications of RET to spectroscopy, as noted above, it is usually significant that the electronically excited donor can in principle release its energy by spontaneous decay, the ensuing fluorescence also being amenable to detection by any suitably placed photodetector. Because the alternative possibility (that of energy being transferred to another chromophore within the system) has such a sharp decline in efficiency as the distance to the acceptor increases, it is common to invoke the critical distance R_0. The Förster rate equation is itself often cast in an alternative form, exactly equivalent to Eq. (15.2), explicitly exhibiting this critical distance (Lakowicz, 1999):

$$w_F = \frac{3\kappa^2}{2}\frac{1}{\tau_{D^*}}\left(\frac{\overline{R}_0}{R}\right)^6 \tag{15.6}$$

Here $\overline{R}_0$ is defined as the Förster radius for which the orientation factor κ^2 would assume its isotropic average value, $^2/_3$ (Valeur, 2002). For complex systems, the angular dependence is quite commonly disregarded and the following simpler expression employed:

$$w_F = \frac{1}{\tau_{D^*}}\left(\frac{R_0}{R}\right)^6 \tag{15.7}$$

leading to a transfer efficiency Φ_T expressed as

$$\begin{aligned}\Phi_\mathrm{T} &= \frac{1}{1+(R/R_0)^6} = 1 - \frac{\tau_\mathrm{fl}}{\tau_{D^*}}\\ &= 1 - \frac{I_\mathrm{fl}}{I_{D^*}}\end{aligned} \tag{15.8}$$

where, I_fl and I_{D^*} are the intensities of the donor fluorescence with the acceptor present and excluded, respectively, and τ_fl specifically denotes the fluorescence lifetime of the donor

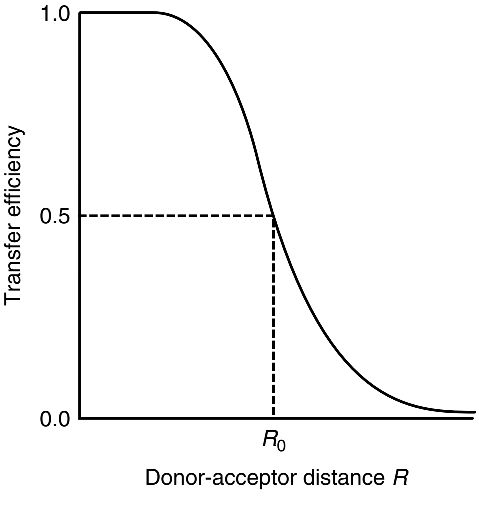

Fig. 15.4 Distance dependence of the transfer efficiency between a pair of chromophores, calculated according to Eq. (15.8).

measured within its RET environment. As graphically depicted in Figure 15.4, a donor–acceptor displacement equal to R_0 corresponds to a transfer efficiency of 50%.

The final equality on the right-hand side of Eq. (15.8), which holds provided decay processes follow single-exponential decay kinetics, provides a formula cast in terms of easily measurable quantities. This is particularly useful because it allows energy transfer efficiencies to be calculated simply on the basis of intensity measurements (for example using a fluorimeter), obviating the separate time-resolved measurements that are otherwise generally necessary for the evaluation of the characteristic decay lifetimes τ_{fl} and τ_{D^*}. When a given electronically excited chromophore is within a distance R_0 of a suitable acceptor, RET will generally be the dominant decay mechanism; conversely, for distances beyond R_0, spontaneous decay (usually fluorescence) will be the primary means of donor deactivation.

15.3.7
Polarization Features

When linearly polarized laser light is used to excite any specific species within a complex disordered solid or liquid system, the probability for excitation of any particular molecule is proportional to $\cos^2\theta$, where θ is the angle between the appropriate excitation transition moment and the electric polarization vector of the input radiation. Consequently, the population of excited molecules has a markedly anisotropic distribution, a phenomenon associated with the term *photoselection*. If radiative decay were to ensue instantaneously, that is, from precisely the initially populated excited level, then the fluorescence would carry the full imprint of that anisotropy and itself exhibit a degree of polarization – the highest value possible. Accounting for the necessary three-dimensional rotational average (Andrews and Thirunamachandran, 1977), it is readily shown that the fluorescence intensity components polarized parallel to and perpendicular to the polarization of the excitation beam, $I_{\parallel}$ and $I_{\perp}$, respectively, would then lie in the ratio 3 : 1. Commonly observed departures from this result thus signify the extent to which the orientation of the emission dipole differs from that of the prior, initial excitation – which may be due to intervening decay, molecular motion, or intermolecular energy transfer.

The two most widely used quantitative expressions of polarization retention are the *fluorescence anisotropy*, r, or the *degree of polarization*, P. Both convey the same information; they are defined and related as follows:

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}}, \quad P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \quad \Rightarrow$$

$$r = \frac{2P}{3 - P} \tag{15.9}$$

The denominator of the expression for r designates the net fluorescence intensity. In a specific situation where the donor and acceptor have transition dipole moments oriented in parallel, then $r = 0.4$ and $P = 0.5$.

A key molecular factor for determining any loss in polarization is the angle θ between the directions of the absorption and emission transition dipole moments. In terms of this parameter and its influence on the measured fluorescence anisotropy, the case where internal decay intervenes between excitation and fluorescence decay within a single molecule is not different from that of a donor–acceptor pair where the absorption and emission processes are spatially separated – provided the donor and acceptor in the latter case have a fixed mutual orientation (the orientation of the pair being random). The following result, derived by (Levshin, 1925) and Perrin (1929) can be applied in both situations:

$$P = \frac{3\cos^2\theta - 1}{3 + \cos^2\theta} \tag{15.10}$$

In the case of a donor–acceptor pair, θ has to be interpreted as the angle θ_T shown in Figure 15.3. Equation (15.10) thus allows direct calculation of this microscopic parameter, through measurement of the macroscopic quantity P. Moreover, when P proves to exhibit a time-dependent decay, a study of the kinetics provides information on the extent of rotational motion intervening between the absorption and the emission events.

Very different behavior is observed for RET systems in which the donor and acceptor are orientationally uncorrelated, that is, where both are independently, randomly oriented. In such cases, there is a very rapid loss of polarization "memory," and it transpires that the associated degree of anisotropy is precisely 1/25, that is, $r = 0.04$ (Agranovich and Galanin, 1982); two or more energy transfer jumps will therefore usually, to all intents and purposes, totally destroy any polarization in any ensuing fluorescence. However, it should be noted that there is a surprising recovery in the anisotropy at distances approaching the transfer wavelength. The effect is sufficiently strong to warrant attention in dilute solution studies.

15.3.8
Diffusion Effects

Till now, only RET between a donor–acceptor pair has been considered. The discussion is now extended to an ensemble of donors D and acceptors A, all units of which are distributed randomly within an n-dimensional volume. For systems in which translational diffusion is extremely slow compared to the rate of energy transfer, the time-dependence of the donor intensity decay at time t, $I_{D^*}(t)$, as obtained by Förster (1959), is given by the following expression:

$$I_{D^*}(t) = I_{D^*}(0) \times \exp\left[-\frac{t}{\tau_{D^*}} - 2\gamma\left(\frac{t}{\tau_{D^*}}\right)^{n/6}\right] \tag{15.11}$$

The most commonly applied form of this expression is when n equals 3, that is, RET in three dimensions. In Eq. (15.11), the parameter γ is explicitly written as

$$\gamma = \frac{2}{3}\pi^{3/2} C_A R_0^3 \tag{15.12}$$

in which C_A is the concentration of acceptors (number per unit volume) and $(4/3)\pi R_0^3 C_A$ represents the average number of acceptor chromophores in a sphere of radius R_0; the orientational factor is again set as $2/3$.

The case where diffusion is comparable to the transfer rate is very complicated, and calculations by Butler and Pilling (1979) have shown that large errors arise on using Förster theory for systems with diffusion coefficients in excess of 10^{-5} cm^2 s^{-1}. To address such systems, a successful approximation was developed by Gösele *et al.* (1975) This approach involves the insertion of a multiplier G within the second term in the exponential of Eq.(15.11). With $n = 3$, the parameter G is given by the following equation:

$$G = \left(\frac{1 + 5.47x + 4.00x^2}{1 + 3.34x} \right)^{3/4} \tag{15.13}$$

in which $x = D(R_0^6/\tau_{D^*})^{-1/3} t^{2/3}$, where D is the mutual diffusion coefficient. In contrast to the Förster theory, the above method provides an excellent approximation – as was fully verified by Butler and Pilling (1979).

15.3.9
Long-Range Transfer

Förster theory is found to be increasingly inaccurate for RET as donor–acceptor distances extend over and beyond 100 Å. It was originally assumed that a "radiative" process accounted for energy transfer over such donor–acceptor separations, and some recent literature on the subject still perpetuate this initial overstatement. Certain sources wrongly treat Förster "radiationless" energy transfer as exact, distinct, and separable from "radiative" energy transfer – the latter signifying successive but independent processes of fluorescence emission by a donor and capture of the ensuing photon by an acceptor.

Although that certainly is the observed character of RET over very long distances – as for example between donor and acceptor components in a dilute solution – it is now known that both "radiative" and Förster transfer are simply the long- and short-range limits of one powerful, all-pervasive mechanism. The latter, determined from quantum electrodynamical calculations, is the outcome of the unified theory of RET (Andrews, 1989). This theory not only embraces Förster and "radiative" energy transfer, but also addresses the intermediate range in which neither of these mechanisms are fully valid. An expression for the total pairwise energy transfer rate, ranging from molecular dimensions up to interstellar distances, is written as

$$w = w_F + w_I + w_{\text{rad}} \tag{15.14}$$

where w_F represents the Förster rate of Eq. (15.2), w_{rad} is the rate of "radiative" energy transfer – explicitly given by the following equation:

$$w_{\text{rad}} = \frac{9\kappa'^2}{8\pi \tau_D R^2} \int F_D(\omega)\sigma_A(\omega)\, d\omega \tag{15.15}$$

and w_I is the intermediate term that is expressed as

$$w_I = \frac{9c^2}{8\pi \tau_D n^2 R^4} (\kappa^2 - 2\kappa\kappa') \times \int F_D(\omega)\sigma_A(\omega) \frac{d\omega}{\omega^2} \tag{15.16}$$

In both Eqs (15.15) and (15.16), the symbol κ' denotes an orientation factor identical to Eq. (15.4) but with the "3" omitted from the second term. In summary, the unified theory of RET contains not only the R^{-6} term of Förster theory and the R^{-2} term denoting the inverse-square law of "radiative" transfer, but also a previously unidentified R^{-4} intermediate term.

15.3.10
Dexter Transfer

Before concluding this section, it is worth observing that other forms of donor–acceptor coupling are also possible, although considerably less relevant to the systems of interest in the following focused account on applications. For example, the transfer of energy between atomic or molecular components with significantly overlapped wavefunctions is usually described in terms of Dexter theory (Dexter, 1953) – where the coupling involves electron exchange and carries an exponential decay with distance, directly reflecting the radial form of overlapping wavefunctions and electron distributions. Unlike Förster transfer, singlet–triplet energy exchange ($^3D^* + ^1A \rightarrow ^1D + ^3A^*$) may also be allowed by the Dexter mechanism. This is because Dexter transfer does not involve transition dipole moments and, thus, is unaffected by the dipole-forbidden character of the transitions $T_1 \rightarrow S_0$ and $S_0 \rightarrow T_1$ within chromophores D and A, respectively. Compared to materials in which the donor and acceptor orbitals do not spatially overlap, such systems are of less use for either device or analytical applications. This is largely because the coupled chromophores lose their electronic and optical integrity, the Dexter mechanism being operational only at very short distances (<10 Å).

15.4
Applications of RET to Molecular Biology

The field in which measurements of RET have undoubtedly had the greatest impact is molecular biology. The importance of RET to this subject, especially in application to biological macromolecules, was first realized following the construction of spectroscopic equipment for routine fluorescence measurements (Steinberg, 1971; Stryer, 1978; dos Remedios, Miki and Barden, 1987; Wu and Brand, 1994). Toward the turn of the twenty-first century, RET underwent a period of significant redevelopment as a spectroscopic technique (Selvin, 2000). This resurgence arose mainly due to the advent of new experimentation methods, for example single-pair RET (Ha *et al.*, 1996), and further advances in instrumentation. The key advantage of RET techniques over others is that fluorescence measurements are highly sensitive, being made against a zero background; moreover, the UV/visible signals are relatively easy to detect, they are specific and the required instrumentation is noninvasive.

15.4.1
Spectroscopic Ruler

A major use of RET, based on its strong distance dependence, exploits its capacity to supply accurate spatial information about molecular structures. This derives from the quantitative assessment of the interchromophore separations, based on comparisons between the corresponding RET efficiencies (Hohng, Joo and Ha, 2004; Schuler, 2005; Koushik *et al.*, 2006; Zhang and Allen, 2007). Such a technique is popularly known as a “spectroscopic ruler.” The elucidations of molecular structure by such means usually lack information on the relative *orientations* of the groups involved, and as an expedient the calculations usually ignore the kappa parameter (Eq. (15.4)). The apparent crudeness of this approach becomes more defensible on realizing that, even if it were to introduce a factor of two inaccuracy, the deduced group spacing would still be in error by only 12% (because $2^{1/6} = 1.12$). Refinements to the theory to accommodate the effect of fluctuations in position or orientation of the participant groups introduce considerable complexity, although progress is being made in several areas (dos Remedios and Moens, 1995; Tanaka, 1998; Yu, 2007; Isaksson *et al.*, 2007; Jang, 2007).

15.4.2
Conformational Change

Through identification of motions in macromolecules, that is, the variation in proximity of one chromophore with respect to another, a number of valuable RET applications arise; including the detection of conformational changes and folding in proteins (Schuler, 2005; Talaga *et al.*, 2000; Heyduk, 2002; Schuler and Eaton, 2008) and the inspection of intracellular protein-protein (Sekar and Periasamy, 2003; Zal and Gascoigne, 2004; Parsons, Vojnovic and Ameer-Beg, 2004; You *et al.*, 2006) and protein-DNA (Hillisch, Lorenz and Diekmann, 2001; Cremazy *et al.*, 2005) interactions (see, for example, Figures 15.5 and 15.6). These and other such processes can be registered by selectively exciting one chromophore using laser light, and monitoring either the decrease in fluorescence from that chromophore or the rise in the generally longer-wavelength fluorescence from the other chromophore as it adopts the role of acceptor. The judicious use of optical dichroic filters can make this RET technique perfectly straightforward (see Figure 15.1). In cases where the two material components of interest do not display suitably overlapped absorption and fluorescence features in an optically accessible wavelength range, molecular tagging with site-specific "extrinsic" (i.e., artificially attached) chromophores can solve the problem. Located at a molecular site of interest, and being selected on the basis of a significant spectral overlap with the counterpart component, such tags can act either in the capacity of donor or acceptor. Lanthanide ions, with their characteristically prominent and linelike absorption features, prove to be particularly valuable in this connection (Selvin, 2002). The semiconductor nanocrystals known as *quantum dots* are also useful in this regard. These crystalline nanoparticles offer several unique traits, including size- and composition-tunable emission from visible to infrared wavelengths, the possibility of a single light source simultaneously exciting different-sized dots, large absorption coefficients across a wide spectral range, and very high level of

photostability (Chan *et al.*, 2002; Clapp, Medintz and Mattoussi, 2006).

15.4.3
Intensity-Based Imaging

Over the past two decades, there has been burgeoning interest in microscopy based on RET (Clegg, 1996; Day, Periasamy and Schaufele, 2001; Wouters, Verveer and Bastiaens, 2001; Hoppe, Christensen and Swanson, 2002; Jares-Erijman and Jovin, 2003), typical instrumentation for which is illustrated in Figure 15.7. There are three specific types of RET method routinely used in the production of biological images. The principles of sensitized-emission RET have already been described (Figure 15.1). For microscopy purposes, this method is fairly inaccurate; no RET donor–acceptor pair is ideal, that is, there will almost always be some overlap between the donor and the acceptor absorbance bands and also the donor and the acceptor emission spectra. Therefore, filters that completely separate these kinds of spectrum are difficult to design. Various calculational algorithms (Gordon *et al.*, 1998; Xia and Liu, 2001; van Rheenen, Langeslag and Jalink, 2004) have been proposed to compensate for this problem, although the methods are complex and no single procedure has received universal acceptance.

A widely used alternative, experimental approach (Karpova *et al.*, 2003; van

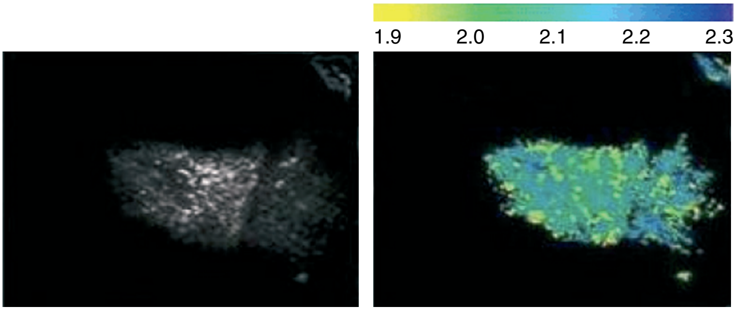
Munster *et al.*, 2005) involves deliberately photobleaching the acceptor, the result of which is complete exclusion of RET. In this method, the donor emission is analyzed before and after the acceptor is bleached by the input of an intense laser beam (at a suitable wavelength). The difference between the donor intensities, with and without the laser input, enables the determination of the transfer efficiency by employing Eq. (15.8). Here, account is taken of spectral bleed-through between the two absorbance bands, and equally between the two emission bands. Signal contamination is still not entirely eliminated, due to a small amount of back-transfer through donor excitation by acceptor emission. Often the main disadvantage in prolonged illumination of the acceptor is the possibility of damage to the sample. Therefore, in practice, photobleaching is seldom appropriate for *in vivo* studies.

15.4.4
Lifetime-Based Imaging

Fluorescence need not be characterized from excitation and emission spectra alone; highly significant information can also be secured from lifetime measurements. Thus, when suitable time-resolved instrumentation is available, the determination of decay kinetics (usually on the nanosecond timescale) enables analysis through resonance energy transfer-based fluorescence lifetime imaging microscopy (FRET-FLIM) (Bastiaens and Squire, 1999; Duncan *et al.*, 2004; Wallrabe and Periasamy, 2005; Peter *et al.*, 2005). In this method, spectral bleed-through is no longer an issue because measurements are made only for the determination of donor lifetimes; back-transfer is usually extremely low, within the noise level. The presence of the acceptor within the local



(a) (b)

Fig. 15.8 MDA-MB-231 cancer cell images recorded with argon laser two-photon excitation, RET microscope based on; (a) intensity and (b) fluorescence lifetime (nanosecond). In the latter image, areas of locally reduced lifetime signify clustered intracellular vesicles. (Adapted from Peter *et al.* (2005).)

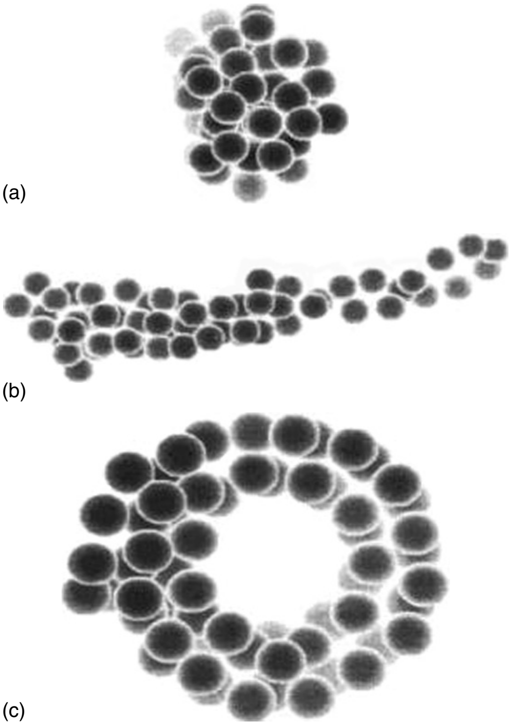


Fig. 15.9 Snapshots of various morphological constructions of a homopolymer chain. The structures (a) – (c) are spherical, rod, and toroidal, respectively. (Adapted from Srinivas and Bagchi (2002).)

environment of the donor influences the fluorescence lifetime of the donor. By measuring the donor lifetime in the presence and the absence of the acceptor, one can accurately calculate the transfer efficiency by use of Eq.(15.8). Drawbacks to FRET-FLIM are the technical challenges the technique presents and the expense of the equipment. Nonetheless, in optical systems that are equipped to provide both intensity and lifetime measurements, a comparison of the two types of image affords a particularly rich source of information, as illustrated by the cancer cell images of Figure 15.8.

15.4.5
Other Applications

Beyond the realm of molecular biology, RET has value in a number of more specifically chemical applications. Two prominent examples are to be found in the fields of synthetic macromolecules and chemical sensors. In polymer science, building on the pioneering principles of Morawetz (1988), RET is now used to determine morphological information on polymer interfaces. Such studies have, for instance, enabled the quantitative characterization of interfacial thickness in polymers of various structures (Farinha and Martinho, 2008). Moreover, RET has been utilized in the study of polymer conformational dynamics. One especially interesting application is the effective differentiation between various collapsed and/or ordered homopolymer chain conformations (spherical, rod and toroidal; as depicted in Figure 15.9) through the associated distribution of transfer effiencies (Srinivas and Bagchi, 2002; Saini, Singh and Bagchi, 2006).

The fabrication of RET-based, analyte-specific sensors has enabled the detection of a variety of species, including dimers of functionalized calixarenes in organic solutions (Castellano *et al.*, 2000), copper(II) in aqueous solution (Cano-Raya, Fernández-Ramos and Capitán-Vallvey, 2006), hydrogen peroxide (Albers, Okreglak and Chang, 2006), phosgene (Zhang and Rudkevich, 2007) and many others. These chemical sensors usually work on the principle of a donor–acceptor system designed such that the presence of the analyte causes the acceptor chromophore to move within closer proximity to a donor, enabling the implementation of an RET process that is not observed in the analyte's absence. Therefore, on irradiation of the system with the relevant chemical present, a strong emission from the acceptor signals the presence of the analyte.

Acknowledgments

We gratefully acknowledge helpful comments from Professor Steve Meech. Research on the theory of RET, at the University of East Anglia, is currently supported by the Leverhulme Trust.

16.1
Introduction

Optics of biological materials determines diagnostic and therapeutic facilities of conventional and laser light. Principle noninvasiveness of low-intensity visible and infrared light, its substantial permeation into biological tissues, and dependence of its propagating properties on tissue morphology and functioning allow for providing structural and functional imaging of many body organs without any risk and limitations. The knowledge of optical properties of tissues and blood is also important for prediction of light–tissue interaction with various follow-up therapeutic effects. Light dosimetry is the key problem in any kind of phototreatment, including cancer treatment using photodynamic or photothermal technologies, as well as laser precise surgery.

In this chapter, optics of biological tissues and blood is briefly discussed. Methods and algorithms for solving the inverse problem of finding tissue and blood optical parameters, such as absorption and scattering coefficients, anisotropy factor, and refractive index are presented. Measuring techniques, such as integrating sphere (IS), spatially resolved, time-resolved, and angular-resolved, optical coherence tomography (OCT), as well as inverse methods, such as inverse adding–doubling (IAD) and inverse Monte Carlo (IMC) are reviewed. Data on optical properties of human tissue and blood measured *in vitro, ex vivo,* and *in vivo* are presented.

16.2
Tissue Optics

16.2.1
Tissue Structure

16.2.1.1 Tissue Optical Models

Biological tissues are optically inhomogeneous and absorbing media. Their average refractive index is higher than that of air, thus partial reflection of the radiation at the tissue/air interface (Fresnel reflection) takes place, while the remaining part of radiation penetrates the tissue. Multiple scattering and absorption are responsible for light beams broadening and eventual decay as they travel through a tissue. The bulk scattering causes a large portion of radiation to be scattered in the backward direction. Light propagation within a tissue depends on the scattering and absorption properties of its compartments:

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

cells, cell organelles, and various fiber structures (Tuchin, 2002; Vo-Dinh, 2003; Tuchin, 2007). The size, shape, and density of these structures, their refractive indices play important roles in the propagation of light in tissues.

The great diversity and structural complexity of tissues require the development of adequate optical models accounting for the scattering and absorption properties of tissues. Two major approaches are currently used: (i) tissue modeled as a medium with a continuous random spatial distribution of optical parameters and (ii) tissue considered as a discrete ensemble of scatterers. The choice of the approach is defined by both the structural specificity of the tissue under study and the kind of light-scattering characteristics that are to be described.

Many tissues can be represented as a random continuum of the inhomogeneities of the refractive index with a varying spatial scale. This approach is applicable for tissues with no pronounced boundaries between elements that feature significant heterogeneity. The process of scattering by these structures may be described under certain conditions using the model of a phase screen (Goodman, 1985; Rytov, Kravtsov and Tatarskii, 1989; Tuchin, 2007).

In accordance with the second approach, biological media are often modeled as ensembles of particles, since many cells and microorganisms are close in shape to spheres, ellipsoids, or rods. A system of noninteracting homogeneous spherical particles is the simplest tissue model. Mie theory rigorously describes the diffraction of light by a spherical particle (Bohren and Huffman, 1983; Born and Wolf, 1999). The further development of this model involves accounting for more complex structure of the spherical particles, namely, the multilayered spheres and the spheres with radial nonhomogeneity, anisotropy, and optical activity (Mishchenko, Hovenier and Travis, 2000; Mishchenko, Travis and Lacis, 2002). Since a connective tissue consists of fiber structures, a system of long cylinders is the most appropriate model for it. Muscular tissue, skin dermis, cerebral membrane (*dura mater*), eye cornea, and sclera belong to this type of tissue formed essentially by collagen fibrils. The solution of the problem of light diffraction in a single homogeneous or multilayered cylinder is also well described (Bohren and Huffman, 1983). Attempts to describe light scattering by a system of interacting particles as a more realistic tissue model (quasi-ordered spherical particles or cylinders) have also been made (see Tuchin, 2007).

16.2.1.2 **Sizing of Tissue and Cell Compartments**

The sizes of cells and tissue structure elements vary in size from a few tenths of nanometers to hundreds of micrometers (Dyson, 1974; Hogan, Alvardo and Weddel, 1971; Silver, 1987; Kessel, 1998; Tuchin, 2002; Vo-Dinh, 2003; Tuchin, Wang and Zimnyakov, 2006; Tuchin, 2007). Blood cells (erythrocytes, leukocytes, and platelets) exhibit the following parameters. A normal erythrocyte in plasma has the shape of a concave–concave disc with a diameter varying from 7.1 to 9.2 μm, a thickness of 0.9–1.2 μm in the center, 1.7–2.4 μm on the periphery, and a volume of $\sim$90 μm^3. Leukocytes are formed like spheres with a diameter of 8–22 μm. Platelets in the blood stream are biconvex disklike particles with diameters ranging from 2 to 4 μm. Normally, blood has about 10 times as many erythrocytes as platelets and about 30 times as many platelets as leukocytes.

Most other mammalian cells have diameters in the range of 5–75 μm. In the epidermal layer, the cells are large (with an average cross-sectional area of about $80\,\mu m^2$) and quite uniform in size. Fat cells, each containing a single lipid droplet that nearly fills the entire cell and therefore results in eccentric placement of the cytoplasm and nucleus, have a wide range of diameters from a few microns to 50–75 μm. Fat cells may reach a diameter of 100–200 μm in pathological cases.

There are a wide variety of structures within cells that determine tissue light scattering. Cell nuclei are on the order of 5–10 μm in diameter; mitochondria, lysosomes, and peroxisomes have dimensions of 1–2 μm; ribosomes are on the order of 20 nm in diameter; and structures within various organelles can have dimensions up to a few hundred nanometers. Usually, the scatterers in cells are not spherical. The models of prolate ellipsoids with a ratio of the ellipsoid axes between 2 and 10 are more typical.

The hollow organs of the body are lined with a thin, highly cellular surface layer of epithelial tissue, which is supported by underlying, relatively acellular connective tissue. In healthy tissues, the epithelium often consists of a single, well-organized layer of cells with en-face diameter of 10–20 μm and height of 25 μm. In dysplastic epithelium, cells proliferate and their nuclei enlarge and appear darker (hyperchromatic) when stained. Enlarged nuclei are primary indicators of cancer, dysplasia, and cell regeneration in most human tissues.

In fibrous tissues or tissues containing fiber layers (cornea, sclera, *dura mater*, muscle, myocardium, tendon, cartilage, vessel wall, retinal nerve fiber layer, etc.) and composed mostly of microfibrils and/or microtubules, typical diameters of the cylindrical structural elements are 10–400 nm. Their length is in a range from 10–25 μm to a few millimeters.

For some tissues, the size distribution of the scattering particles may be essentially monodispersive and for others it may be quite broad. Examples for the two are transparent eye cornea stroma, which has a sharply monodispersive distribution, and turbid eye sclera, which has a rather broad distribution of collagen fiber diameters.

16.2.2
Light Interaction with Tissues

16.2.2.1 Light Absorption and Scattering

Absorbed light is converted to heat or radiated in the form of fluorescence, it is also consumed in photobiochemical reactions. The absorption spectrum depends on the type of predominant absorption centers and water content of tissues. Absolute values of absorption coefficients for typical tissues lie in the range of 10^{-2}–$10^{4}\ \text{cm}^{-1}$ (Anderson and Parrish, 1982; Chance, 1989; Duck, 1990; Frank and Kessler, 1992; Henderson and Dougherty, 1992; Welch and van Gemert, 1992; Niemz, 1996; Tuchin, 2002; Berlien and Mueller, 2003; Vo-Dinh, 2003; Tuchin, 2007). In the ultraviolet (UV) and infrared (IR) ($\lambda \geq 2000$ nm) spectral regions, light is readily absorbed, which accounts for the small contribution of scattering and inability of radiation to penetrate deep into tissues (only through one or two cell layers). Short-wave visible light penetrates typical tissues as deep as 0.5–2.5 mm, whereupon it undergoes an *e*-fold decrease of intensity. In this case, both scattering and absorption occur, with 15–40% of the incident radiation being reflected. In the wavelength range of 600–1600 nm, scattering prevails over absorption, and light penetrates to a depth of 8–10 mm. Simultaneously, the intensity of the reflected radiation increases to 35–70% of the total incident light (due to backscattering).

Absorption spectrum of biological material is expressed usually in terms of the wavelength dependence of absorption coefficient. Such spectra for some tissues and tissue components: water (75%), aorta, skin, epidermis, melanosome, and whole blood are presented in Figure 16.1. The often-used lasers and their wavelengths are presented on the crossings of water-absorption curve, the corresponding laser wavelengths showing what absorption coefficient is expected on absorption in water. Since water is the major component of any soft tissue, presented absorption coefficients will be only slightly corrected for real tissues. As shown in Figure 16.1, for bloodless skin in the visible range, absorption is equal to water (75%), since dermis as the main skin component that is well supplied by water defines absorption coefficient of whole skin in this range.

Light interaction with multilayer and multicomponent tissues, such as skin

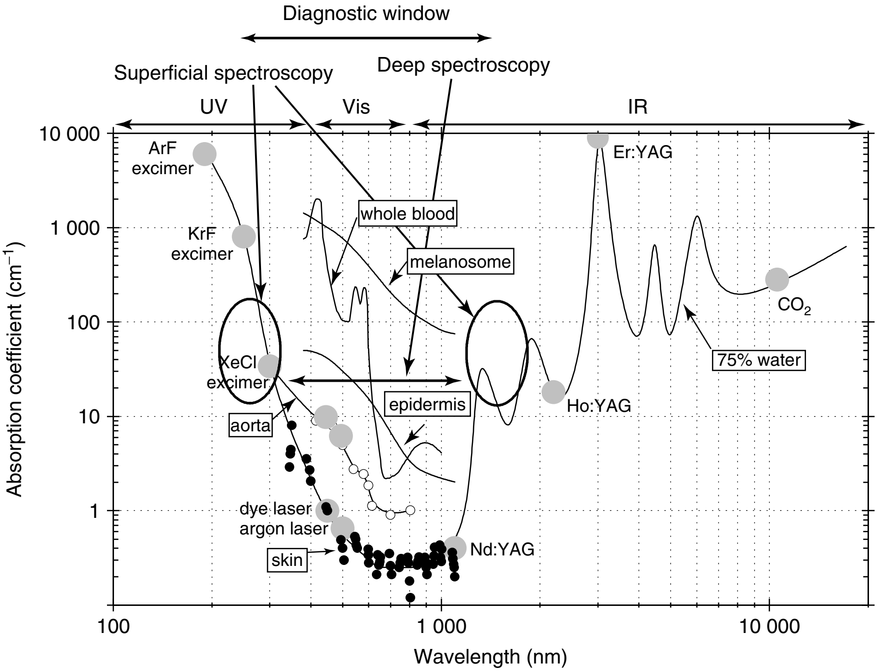

Fig. 16.1 Absorption spectra of some tissues and tissue components: water (75%), aorta, skin, epidermis, melanosome, and whole blood; lasers and their wavelengths as well as diagnostic window and wavelength ranges suitable for superficial and deep spectroscopy are also shown (Tuchin, 2007).

of female breast, is a very complicated process. In skin, the horny layer (stratum corneum (SC)) reflects about 5–7% of the incident light. A collimated light beam is transformed to a diffuse one by microscopic inhomogeneities at the air/horny layer interface. A major part of reflected light results from backscattering in different skin layers (SC, epidermis, dermis, blood, and percutaneous fat). The absorption of diffuse light by skin pigments is a measure of bilirubin content, hemoglobin concentration and its saturation with oxygen, and the concentration of pharmaceutical products in blood and tissues; these characteristics are widely used in the diagnosis of various diseases (Tuchin, 2002; Vo-Dinh, 2003; Tuchin, 2007). Certain diagnostic modalities take advantage of ready transdermal penetration of visible and near-infrared (NIR) light inside the body in the wavelength region corresponding to the diagnostic/therapeutic window (600–1600 nm).

16.2.2.2 **Theoretical Description for CW**

A collimated (laser) beam is attenuated in a thin tissue layer of thickness d in accordance with the exponential law, Bouguer-Beer-Lambert law (Tuchin, 2002; Vo-Dinh, 2003; Tuchin, 2007):

$$I(d) = (1 - R_F) I_0 \exp(-\mu_t d) \qquad (16.1)$$

where $I(d)$ is the intensity of transmitted light measured using a distant photodetector with a small aperture (online or collimated transmittance) in W cm^{-2}; R_F is the coefficient of Fresnel reflection; at the normal beam incidence, $R_F = [(n - l)/(n + l)]^2$; n is the relative mean refractive index of tissue and surrounding media; I_0 is the incident light intensity in W cm^{-2};

$$\mu_t = \mu_a + \mu_s \qquad (16.2)$$

is the extinction coefficient (interaction or total attenuation coefficient) in cm^{-1}, where μ_a is the absorption coefficient in cm^{-1}, and μ_s is the scattering coefficient in cm^{-1}. Strictly speaking, Eq. (16.1) is valid only for a highly absorbing biological media, when $\mu_a \gg \mu_s$.

The extinction coefficient is connected with the extinction cross section σ_{ext} as

$$\mu_t = \rho_s \sigma_{\text{ext}} \qquad (16.3)$$

where ρ_s is the density of particles (tissue and cell compounds). For a system of particles with absorption,

$$\sigma_{\text{ext}} = \sigma_{\text{sca}} + \sigma_{\text{abs}} \qquad (16.4)$$

and

$$\mu_s = \rho_s \sigma_{\text{sca}} \quad \mu_a = \rho_s \sigma_{\text{abs}} \qquad (16.5)$$

The average scattering cross section per particle can be presented in the form suitable for experimental evaluations (Bohren and Huffman, 1983):

$$\sigma_{\text{sca}} = \frac{\lambda^2}{2\pi} \frac{1}{I_0} \int_0^{\pi} I(\theta) \sin\theta \, d\theta \qquad (16.6)$$

where I_0 is the intensity of the incident light, $I(\theta)$ is the angular distribution of the scattered light by a particle, and θ is the scattering angle.

The mean free path (MFP) length between two interactions is denoted by

$$l_{\text{ph}} = \mu_t^{-1} \qquad (16.7)$$

To analyze light propagation under multiple scattering conditions, it is assumed that absorbing and scattering centers are uniformly distributed across the tissue.

Visible and NIR radiation is normally subject to anisotropic scattering characterized by a clearly apparent direction of photons undergoing single scattering, which may be due to the presence of large cellular organelles (mitochondria, lysosomes, and inner membranes (Golgi apparatus)) (Tuchin, 2002, 2007).

When the scattering medium is illuminated by unpolarized light and/or only the intensity of multiply scattered light needs to be computed, a sufficiently strict mathematical description of continuous wave (CW) light propagation in a medium is possible in the framework of the scalar stationary radiation transfer theory (RTT) (Chandrasekhar, 1960; van de Hulst, 1980, 1981; Ishimaru, 1997; Mishchenko, Travis and Lacis, 2000, 2002, 2006; Müller *et al.*, 1993; Niemz, 1996; Sobolev, 1974; Thomas and Stamnes, 1999; Tuchin, 2002, 2007; Tuchin, Wang and Zimnyakov, 2006; Vo-Dinh, 2003; Wang and Wu, 2007; Welch and van Gemert, 1992; Yanovitskij, 1997; Zege, Ivanov and Katsev, 1991). The theory is valid for an ensemble of scatterers located far from one another and has been successfully used to work out many practical problems of tissue optics. The main stationary equation of RTT for monochromatic light has the form

$$\frac{\partial I(\bar{r},\bar{s})}{\partial s} = -\mu_t I(\bar{r},\bar{s}) + \frac{\mu_s}{4\pi} \times \int_{4\pi} I(\bar{r},\bar{s}')p(\bar{s},\bar{s}')d\Omega' \quad (16.8)$$

where $I(\bar{r},\bar{s})$ is the radiance (or specific intensity) – average power flux density at a point $\bar{r}$ in the given direction $\bar{s}$ (W cm^{-2}sr); $p(\bar{s},\bar{s}')$ is the scattering phase function, 1/sr; and $d\Omega'$ is the unit solid angle about the direction $\bar{s}'$, sr. It is assumed that there are no radiation sources inside the medium.

For practical purposes, integrals of the function $I(\bar{r},\bar{s})$ over certain phase space regions $(\bar{r},\bar{s})$ are of greater value than the function itself. Specifically, optical probes of tissues frequently measure the outgoing light distribution function at the medium surface, which is characterized by the radiant flux density or irradiance (W cm^{-2}):

$$F(\bar{r}) = \int_{(\bar{s}\overline{N})>0} I(\bar{r},\bar{s})(\bar{s}\overline{N})d\Omega \quad (16.9)$$

where $\overline{N}$ is the outside normal vector to the domain boundary surface.

In problems of optical dosimetry in tissues, the measured quantity is actually the total radiant energy fluence rate $U(\bar{r})$. It is the sum of the radiance over all angles at a point $\bar{r}$ and is measured by watts per square centimeter:

$$U(\bar{r}) = \int_{4\pi} I(\bar{r},\bar{s})d\Omega \quad (16.10)$$

The phase function $p(\bar{s},\bar{s}')$ describes the scattering properties of the medium and is, in fact, the probability density function for scattering in the direction $\bar{s}'$ of a photon traveling in the direction $\bar{s}$; in other words, it characterizes an elementary scattering act. If scattering is symmetric relative to the direction of the incident wave, then the phase function depends only on the scattering angle θ (angle between directions $\bar{s}$ and $\bar{s}'$), that is,

$$p(\bar{s},\bar{s}') = p(\theta) \quad (16.11)$$

The assumption of random distribution of scatterers in a medium (i.e., the absence of spatial correlation in the tissue structure) leads to normalization

$$\int_0^{\pi} p(\theta)2\pi \ \sin\theta \, d\theta = 1 \tag{16.12}$$

In practice, the phase function is usually well approximated with the aid of the postulated Henyey–Greenstein function:

$$p(\theta) = \frac{1}{4\pi} \cdot \frac{1-g^2}{(1+g^2-2g\ \cos\ \theta)^{3/2}} \tag{16.13}$$

where g is the scattering anisotropy parameter (mean cosine of the scattering angle θ).

$$g \equiv \langle \cos\ \theta \rangle = \int_0^{\pi} p(\theta) \cos\ \theta \cdot 2\pi \sin\ \theta \, d\theta \tag{16.14}$$

The value of g varies in the range from -1 to 1 : $g = 0$ corresponds to isotropic (Rayleigh) scattering, $g = 1$ to total forward scattering (Mie scattering at large particles), and -1 to total backward scattering.

The integro-differential Eq. (16.8) is too complicated; therefore, it is frequently simplified by representing the solution in the form of spherical harmonics. Such simplification leads to a system of $(N+1)^2$ connected differential partial derivative equations known as the P_N approximation. This system is reducible to a single differential equation of order $(N+1)$. For example, four connected differential equations reducible to a single diffusion-type equation are necessary for $N = 1$. It has the following form for an isotropic medium:

$$\left(\nabla^2 - \mu_{\text{eff}}^2\right) U(\bar{r}) = -Q(\bar{r}) \tag{16.15}$$

where

$$\mu_{\text{eff}} = [3\mu_a(\mu_s{}' + \mu_a)]^{1/2} \tag{16.16}$$

is the effective attenuation coefficient or inverse diffusion length, $\mu_{\text{eff}} = 1/l_d$ in cm^{-1};

$$Q(\bar{r}) = (cD)^{-1}q(\bar{r}) \tag{16.17}$$

$q(\bar{r})$ is the source function (i.e., the number of photons injected into the unit volume),

$$D = \frac{1}{3(\mu_s{}' + \mu_a)} \tag{16.18}$$

is the photon diffusion coefficient in cm^2/c;

$$\mu_s{}' = (1-g)\mu_s \tag{16.19}$$

is the reduced (transport) scattering coefficient in cm^{-1}, and c is the velocity of light in the medium. The transport mean free path (TMFP) of a photon (centimeters) is defined as

$$l_t = \frac{1}{\mu_t{}'} = (\mu_a + \mu_s{}')^{-1} \tag{16.20}$$

where $\mu_t{}' = \mu_a + \mu_s{}'$ is the transport coefficient. The TMFP is the distance over which the photon loses its initial direction. It is worthwhile to note that the TMFP in a medium with anisotropic single scattering significantly exceeds the MFP in a medium with isotropic single scattering $l_t \gg l_{\text{ph}}$.

The diffusion approximation is inapplicable for light beam input near the object's surface where single or low-step scattering prevails. When a narrow light beam normally incident upon a semi-infinite turbid medium with anisotropic scattering, it can be considered as converted into an isotropic point source at the depth of one TMFP below the surface.

The refractive index variation in tissues is quantified by the ratio $m \equiv n_s/n_0$, where n_s and n_0 are the index of refraction of scattering particles and background material, respectively. This ratio determines light-scattering efficiency. For example, in a simple monodisperse tissue model, such as dielectric spheres of equal diameter $2a$, the reduced scattering coefficient (Graaff *et al.*, 1992):

$$\mu_s' = 3.28\pi a^2 \rho_s \frac{2\pi a}{\lambda}^{0.37} (m-1)^{2.09} \tag{16.21}$$

where λ is the light wavelength in the scattering medium. This equation is valid for noninteracting Mie scatterers, $g > 0.9$; $5 < 2\pi a/\lambda < 50$; $1 < m < 1.1$. It gives dependencies of reduced scattering coefficient on refractive index mismatch (m), particle size (a), density (ρ_s), and wavelength (λ).

Basing on diffusion approximation attenuation of a light (laser) beam of intensity I_0 at depths $z \geq l_t$ in a thick tissue may be described as

$$I(z) \approx I_0 b_s \exp(-\mu_{\text{eff}} z) \tag{16.22}$$

where b_s accounts for additional irradiation of upper layers of a tissue due to backscattering (photon recycling effect). Respectively, the depth of light penetration into a tissue is

$$l_e = l_d[ln\ b_s + 1] \tag{16.23}$$

Typically, for tissues $b_s = 1\text{–}5$ for beam diameter of 1–20 mm (Star, Wilson and Patterson, 1992). Thus, when wide laser beams are used for irradiation of highly scattering tissues with low absorption, light energy is accumulated in tissue due to high multiplicity of chaotic long-path photon migrations. The light-power density within the superficial tissue layers may substantially (up to fivefold) exceed the incident power density.

Measurement of diffusely reflected light is often used to evaluate bulk tissue optical properties. To solve diffusion equation, the boundary conditions are derived by considering Fresnel's laws of reflection and balancing the fluence rate and photon flow crossing the interface. For the source term modeled as a point scattering source and extrapolated boundary approach satisfying the boundary condition, the spatially resolved steady-state reflectance per incident photon, $R(r_{\text{sd}})$, is expressed as (Farrell and Patterson, 2001):

$$\begin{aligned} R(r_{\text{sd}}) = {} & \frac{F_U}{4\pi}\left\{l_t\left(\mu_{\text{eff}} + \frac{1}{r_1}\right)\right. \\ & \times \frac{\exp(-\mu_{\text{eff}} r_1)}{r_1^2} + (l_t + 2z_b) \\ & \left.\times \left(\mu_{\text{eff}} + \frac{1}{r_2}\right)\frac{\exp(-\mu_{\text{eff}} r_2)}{r_2^2}\right\} \\ & + \frac{F_F}{4\pi D}\left\{\frac{\exp(-\mu_{\text{eff}} r_1)}{r_1}\right. \\ & \left. - \frac{\exp(-\mu_{\text{eff}} r_2)}{r_2}\right\} \end{aligned} \tag{16.24}$$

where r_{sd} is the distance between light source and detector at the tissue surface (source–detector separation), cm; $r_1 = \sqrt{l_t^2 + r_{\text{sd}}^2}$; $r_2 = \sqrt{(l_t + 2z_b)^2 + r_{\text{sd}}^2}$; $z_b = 2AD$ is the distance to the extrapolated boundary, $A = (1 + R_{\text{eff}})/(1 - R_{\text{eff}})$, R_{eff} is the effective reflection coefficient, which can be found by integrating the Fresnel reflection coefficient over all incident angles; and D is the diffusion coefficient. The parameters F_U and F_F represent the fractions of the fluence rate and the flux, which exit the tissue across the interface. These values are obtained by integration of the radiance over the backward hemisphere and depend on refractive index mismatch on the boundary.

16.2.2.3 Index of Refraction of Tissue Compartments

The mean refractive index $\overline{n}$ of a tissue is defined by the refractive indices of its scattering particle material n_s and ground (surrounding) matter n_0. The refractive indices of tissue structure elements and the tissue itself, can be derived using the law of Gladstone and Dale, which states that the resulting value represents an average of the refractive indices of the components related to their volume fractions as (Tuchin, 2002, 2007):

$$\overline{n} = \sum_{i=1}^{N} n_i f_i \quad \sum_i f_i = 1 \tag{16.25}$$

where n_i and f_i are the refractive index and volume fraction of the individual components, respectively, and N is the number of components.

Soft tissue is composed of closely packed groups of cells entrapped in a network of fibers through which water percolates. At a microscopic scale, the tissue components have no pronounced boundaries. They appear to merge into a continuous structure with spatial variations in the refractive index. To model such a complicated structure as a collection of particles, it is necessary to resort to a statistical approach.

It has been shown that the tissue components that contribute most to the local refractive-index variations are the connective tissue fibers (bundles of elastin and collagen), cytoplasmic organelles (mitochondria, lysosomes, and peroxisomes), cell nuclei, and melanin granules. The average background index is defined as the weighted average of refractive indices of the cytoplasm and the interstitial fluid, n_{cp} and n_{is}, as

$$\overline{n}_0 = f_{\mathrm{cp}} n_{\mathrm{cp}} + (1 - f_{\mathrm{cp}}) n_{\mathrm{is}} \tag{16.26}$$

where f_{cp} is the volume fraction of the fluid in the tissue contained inside the cells. Accounting for typical experimental data as $n_{\mathrm{cp}} = 1.367$ and $n_{\mathrm{is}} = 1.355$, and that approximately 60% of the total fluid in soft tissue is contained in the intracellular compartment, it follows from Eq. (16.26) that $\overline{n}_0 = 1.362$. The refractive index of scattering particle material can be determined as the sum of the background index and index variation components (Tuchin, 2007):

$$\overline{n}_s = \overline{n}_0 + f_f(n_f - n_{\mathrm{is}}) + f_{\mathrm{nc}}(n_{\mathrm{nc}} - n_{\mathrm{cp}}) + f_{\mathrm{or}}(n_{\mathrm{or}} - n_{\mathrm{cp}}) \tag{16.27}$$

where the subscripts f, is, nc, cp, and or refer to the fibers, interstitial fluid, nuclei, cytoplasm, and organelles, which are the major contributors to index variations. The terms in parentheses in this expression are the differences between the refractive indices of the three types of tissue component and their respective backgrounds; the multiplying factors are the volume fractions of the elements in the solid portion of the tissue. The refractive index of the connective-tissue fibers is about 1.47, which corresponds to about 55% hydration of collagen, its main component. Taking into account that $n_{\mathrm{nc}} \cong n_{\mathrm{or}} = 1.40$, the mean index variation can be expressed in terms of the fibrous-tissue fraction c_f only:

$$\overline{n}_s = \overline{n}_0 + f_f(n_f - n_{\mathrm{is}}) + (1 - f_f) \times (n_{\mathrm{nc}} - n_{\mathrm{cp}}) \tag{16.28}$$

Collagen and elastin fibers compose approximately 70% of the fat-free dry weight of the dermis, 45% of the heart, and 2–3% of the nonmuscular internal organs (Schmitt and Kumar, 1998). Therefore, depending on tissue type, f_f may be as small as about 0.02 or as large as 0.7. For $n_f - n_{\text{is}} = 1.470 - 1.355 = 0.115$ and $n_{\text{nc}} - n_{\text{cp}} = n_{\text{or}} - n_{\text{cp}} = 1.400 - 1.367 = 0.033$, the mean index variations that correspond to these two extremes are $\overline{n}_s = 1.397$ and 1.452. Indeed, for some hard tissues or melanin granules in skin or eye iris, refractive index of scatterers could be as high as 1.5–1.7.

Measuring refractive indices in tissues and their constituent components is an important focus of interest in tissue optics because index of refraction determines light reflection and refraction at the interfaces between air and tissue, detecting fiber and tissue, and tissue layers; it also strongly influences light propagation and distribution within tissues, defines speed of light in tissue, and governs how the photons migrate (Tuchin, 2007). Although these studies have a rather long history (Duck, 1990), the mean values of refractive indices for many tissues are missing in the literature. According to Duck, most of them have refractive indices for visible light in the 1.335–1.620 range (e.g., 1.55 in the SC, 1.620 in the enamel, and 1.386 at the lens surface). It is worthwhile noting that *in vitro* and *in vivo* measures may differ significantly. For example, the refractive index in rat mesenteric tissue *in vitro* was found to be 1.52 compared with only 1.38 *in vivo*. This difference can be accounted for by the decreased refractivity of ground matter, n_0, due to impaired hydration.

The optical properties of tissues, including refractive indices, are known to depend on water content. Tissue is modeled as a mixture of water and a bioorganic compound of a tissue. For instance, the refractive index of human skin can be approximated by a 70/30 mixture of water and protein (Troy and Thennadil, 2001). Assuming that protein has a constant refractive index value of 1.5 over the entire wavelength range, the following expression for estimation of skin index of refraction was suggested:

$$\begin{aligned} n_{\text{skin}}(\lambda) &= 0.7(1.58 - 8.45 \times 10^{-4}\lambda + 1.10 \\ &\quad \times 10^{-6}\lambda^2 - 7.19 \times 10^{-10}\lambda^3 + 2.32 \\ &\quad \times 10^{-13}\lambda^4 - 2.98 \times 10^{-17}\lambda^5) \\ &\quad + 0.3 \cdot 1.5 \end{aligned} \tag{16.29}$$

where wavelength λ is in nanometers.

16.2.2.4 **Short Pulse Interaction with Biomaterials**

When probing the plane-parallel layer of a scattering medium (biomaterial) with an ultrashort laser pulse, the transmitted pulse consists of a ballistic component, a group of photons having zigzag trajectories, and a highly intensive diffuse component (Müller *et al.*, 1993; Tuchin, 2007). Both unscattered photons and photons undergoing forward-directed single-step scattering contribute to the intensity of the ballistic component. This component is subject to exponential attenuation with increasing sample thickness (see Eq. (16.1)), thus, has a limited utility for practical diagnostic purposes in medicine. The group of snake photons with zigzag trajectories includes photons that have experienced only a few collisions each. They propagate along trajectories that deviate only slightly from the direction of the incident beam and form the first-arriving to detector part of the diffuse component.

These photons carry information about the optical properties of the biomaterial and parameters of any foreign object (i.e., tumor), which they may happen to come across during their travel.

Typically for many scattering biomaterials, the diffuse component is very broad and intense since it contains the bulk of incident photons after they have participated in many scattering acts and therefore migrate in different directions and have different path lengths. Moreover, the diffuse component carries information about the optical properties of the scattering medium, and its deformation may reflect the presence of local inhomogeneities in the medium. The resolution obtained by this method at a high light-gathering power is much lower than in the method measuring straight-passing photons. Two probing schemes are conceivable, one recording transmitted photons and the other taking advantage of their backscattering. If in the diffusion approximation (valid at $\mu_a \ll \mu_s{}'$), the tissue is homogeneous and semi-infinite, the size of both the source and the detector is small compared with the distance r_{sd} between them at the tissue surface, and the pulse may be regarded as single, then the light distribution is described by the time-dependent diffusion equation (Müller *et al.*, 1993; Tuchin, 2002, 2007):

$$\left(\nabla^2 - c\mu_a D^{-1} - D^{-1}\frac{\partial}{\partial t}\right) \cdot U(\bar{r}, t) = -Q(\bar{r}, t) \qquad (16.30)$$

which is, in fact, the generalization of the CW Eq. (16.15). Solving Eq. (16.30) yields the following relation for the number of backscattered photons at the surface for unit time and from unit area $R(r_{\mathrm{sd}}, t)$ (Jacques, 1989; Patterson, Chance and Wilson, 1989)

$$R(r_{\mathrm{sd}}, t) = \frac{z_0}{(4\pi D)^{3/2}} t^{-5/2} \times \exp\left(-\frac{r_{\mathrm{sd}}^2 + z_0^2}{2Dt}\right) \exp(-\mu_a ct) \qquad (16.31)$$

and correspondingly for transmittance

$$\begin{aligned} T(r_{\mathrm{sd}}, d, t) &= (4\pi D)^{-3/2} t^{-5/2} \exp\frac{-r_{\mathrm{sd}}^2}{4Dt} \\ &\times \left\{(d - z_0) \exp\left[-\frac{(d - z_0)^2}{4Dt}\right]\right. \\ &- (d + z_0) \exp\left[-\frac{(d + z_0)^2}{4Dt}\right] \\ &+ (3d - z_0) \exp\left[-\frac{(3d - z_0)^2}{4Dt}\right] \\ &\left. - (3d + z_0) \exp\left[-\frac{(3d + z_0)^2}{4Dt}\right]\right\} \\ &\times \exp(-\mu_a ct) \end{aligned} \qquad (16.32)$$

where $z_0 = (\mu_s{}')^{-1}$ and d is the tissue thickness.

In practice, μ_a and $\mu_s{}'$ are estimated by fitting Eq. (16.31) or Eq. (16.32) with the shape of a pulse measured by the time-resolved photon counting technique. Experimentally measured optical parameters of many tissues and model media obtained by the pulse method can be found in Cheong, Prahl and Welch (1990); Welch and Gemert (1992); Müller *et al.* (1993); Roggan *et al.* (1995); Tuchin (2002); Vo-Dinh (2003); Tuchin (2007). An important advantage of the pulse method is its applicability to *in vivo* studies owing to the possibility of the separate evaluation of μ_a and $\mu_s{}'$ using a single measurement in the backscattering or transillumination regimes.

Many studies are also devoted to image transfer in tissues and the evaluation of the resolving power of optical tomographic schemes making use of the first-transmitted photons of ultrashort pulses (Müller *et al.*, 1993; Tuchin, 2002; Vo-Dinh, 2003; Tuchin, 2007). A contrast image of an object in a scattering medium can be provided by electronical or optical time-gating of the earliest-arriving, minimally scattered light (ballistic and snake photons), which contains geometric information. The first group of schemes uses the electronic time-gating procedure. The time-correlated single-photon counting technique explores a high-repetition rate picosecond laser (e.g., a cavity-dumped mode-locked dye laser). At the detection of the firstly arrived photons, the time delay is measured with a time-to-amplitude converter and a histogram of the arrival times is built up using a large number of low-energy pulses. The time resolution of such a technique is limited to about 50 picoseconds. For more energetic pulses from lasers with a lower repetition rate, the usage of the streak cameras allows for a time resolution down to 1 picosecond. If a synchroscan streak camera is employed, even a high-repetition rate source with low-energy pulses can be used.

The second group of techniques uses the optical nonlinear effects to select photons. For a scheme with an optical Kerr gate, an energetic laser is used. Part of the pulse is transmitted into the tissue and part is used to open the shutter by utilizing the optical Kerr effect (i.e., the cell with CS_2). Since the gate width is determined by the length of the laser pulse only, subpicosecond gate times can be achieved. The Raman amplifier gating technique also uses energetic laser pulses. A Stokes wave generated by stimulated Raman scattering in a gas cell is used to probe the tissue. The low-intensity transmitted light is amplified in a Raman amplifier, which in turn is pumped by an ultrashort laser pulse. This pulse has the proper time delay to strobe on the desired early temporal part of the light under investigation. The third group of schemes uses a time-correlated frequency doubling technique and is frequently used in optical autocorrelators for monitoring laser pulse characteristics. It can be used directly for optical gating of signal photons.

16.3
Measurements of Optical Properties of Tissues and Blood

16.3.1
Introduction

Methods for determining the optical parameters of tissues can be divided into two large groups, direct and indirect methods (Tuchin, 2007). Direct methods include those based on some fundamental concepts and rules such as the Bouguer–Beer–Lambert law (see Eq. (16.1)), the single-scattering phase function (see Eqs. (16.11) and (16.13)) for thin samples, or the effective light penetration depth for slabs. The parameters measured are the collimated light transmission T_c and angular dependence of the scattered light intensity $I\ (\theta)$ in W cm^{-2}sr, for thin samples or the fluence rate inside a slab. The normalized scattering angular dependence is equal to the scattering phase function $I\ (\theta)/I(0) \equiv p(\theta)$, 1/sr. These methods are advantageous in that they use very simple analytic expressions for data processing. Their disadvantages are related to the necessity to strictly fulfill experimental conditions dictated by the selected model (single scattering in thin samples, exclusion of the effects of light polarization and refraction at cuvette edges, and so on; in the case of slabs with multiple scattering, the recording detector must be placed far from both the light source and the medium boundaries.

Indirect methods obtain the solution of the inverse scattering problem using a theoretical model of light propagation in a medium. They are in turn divided into iterative and noniterative models. The noniterative models use equations in which the optical properties are defined through parameters directly related to the quantities being evaluated. They are based on the two-flux or multiflux models. In indirect iterative methods, the optical properties are implicitly defined through measured parameters. Quantities determining the optical properties of a scattering medium are enumerated until the estimated and measured values for reflectance and transmittance coincide with the desired accuracy. These methods are cumbersome, but the optical models currently in use may be even more complicated than those underlying noniterative methods (examples include the diffusion theory (DT), IAD, and IMC methods) (see Tuchin, 2007).

The optical parameters of tissue samples (μ_a, μ_s, and g) are measured by different methods. *In vitro* evaluation is most often achieved by the double-integrating sphere (DIS) method combined with collimated transmittance measurements. This approach implies either sequential or simultaneous determination of three parameters: collimated transmittance $T_c = I(d)/I(0)$ (see Eq. (16.1)), total transmittance $T_t = T_c + T_d$ (T_d being diffuse transmittance), and diffuse reflectance R_d. The optical parameters of the tissue are deduced from these measurements using different theoretical expressions or numerical methods (two-flux and multiflux models, the IMC or IAD methods) relating μ_a, μ_s, and g to the parameters being investigated.

Any three measurements from the following five are sufficient for the evaluation of all three optical parameters (Cheong, Prahl and Welch, 1990): (i) total (or diffuse) transmittance for collimated or diffuse radiation; (ii) total (or diffuse) reflectance for collimated or diffuse radiation; (iii) absorption by a sample placed inside an IS; (iv) collimated transmittance (of unscattered light); (v) angular distribution of radiation scattered by the sample. Iterative methods normally take into account discrepancies between refractive indices at sample boundaries as well as the multilayer nature of the sample. The following factors are responsible for the errors in the estimated values of optical coefficients and need to be borne in mind in a comparative analysis of optical parameters obtained in different experiments: (i) physiological conditions of tissues (the degree of hydration, homogeneity, species-specific variability, frozen/thawed or fixed/unfixed state, *in vitro*/*in vivo* measurements, smooth/rough surface); (ii) geometry of irradiation; (iii) matching/mismatching interface refractive indices; (iv) orientation of detecting optical fibers inside the sample relative to the source fibers; (v) numerical aperture of the recording fibers; (vi) angular resolution of photodetectors; (vii) separation of radiation experiencing forward scattering from unscattered radiation; and

(viii) theory used to solve the inverse problem.

16.3.2
Integrating Sphere Technique

One of the indirect methods to determine optical properties of tissues *in vitro* is the IS technique. Diffuse reflectance R_d, total transmittance T_t, and collimated transmittance T_c are measured. In general, absorption coefficient μ_a, scattering coefficient μ_s, and anisotropy factor g can be obtained from these data using an inverse method based on the radiative transfer theory (see Eq. (16.8)). When the scattering phase function $p(\theta)$ is available from goniophotometry, g can be readily calculated. In this case, for the determination of μ_a and μ_s, it is sufficient to measure R_d and T_t only. Sometimes in experiments with tissue and blood samples, a DIS configuration is preferable, since in this case both reflectance and transmittance can be measured simultaneously and less degradation of the sample is expected during measurements.

The IS technique was used by a number of investigators to determine the absorption coefficient, the scattering coefficient, the anisotropy factor, and/or the reduced scattering coefficient of tissues and blood (see Tuchin, 2007). Barium-sulfate or Spectralon® ISs are used in the experiments. As monochromatic light sources, a laser, an Xe-lamp, and/or a Hg-lamp combined with monochromator are used, while a photomultiplier or an Si-photodiode is employed as a detector. Sometimes, a white light source is used as irradiator and charge-coupled device (CCD) fiber-optic spectrometer as a detector.

16.3.3
Multiflux Approach

To separate the light beam attenuation due to absorption from the loss due to scattering, the one-dimensional, two-flux Kubelka-Munk model (KMM) can be used as the simplest approach to solve the problem. This approach has been widely used to determine the absorption and scattering coefficients of biological tissues, provided the scattering is significantly dominant over the absorption (see Tuchin, 2007). The KMM assumes that light incident on a slab of tissue because of interaction with the scattering media can be modeled by two fluxes, counterpropagating in the tissue slab. The optical flux, which propagates in the same direction as the incident flux, is decreased by absorption and scattering processes and is also increased by backscattering of the counterpropagating flux in the same direction. Changes in counterpropagating flux are determined in an analogous manner. The fraction of each flux lost by absorption per unit path length is denoted as K, while the fraction lost due to scattering is called S. The main assumptions of the KMM: K and S parameters are assumed to be uniform throughout the tissue slab; all light fluxes are diffuse; and the amount of light lost from the edges of the sample during reflectance measurements is negligible. Basic KMM does not account for reflections at boundaries at which index of refraction mismatches exist. Following the KMM and diffusion approximation of the RTT, the KMM parameters were expressed in terms of light transport theory: the absorption and scattering coefficients and scattering anisotropy factor (Cheong, Prahl and

Welch, 1990). Often, such simple methods as the KMM, are used as the first step of the inverse algorithm for estimation of the optical properties of tissues.

16.3.4
The Inverse Adding–Doubling Method

The IAD method provides a tool for the rapid and accurate solution of inverse scattering problem. It is based on the general method for the solution of the transport equation (see Eq. (16.8)) for plane-parallel layers suggested by van de Hulst (1980) and introduced to tissue optics by Prahl, van Gemert and Welch (1993). An important advantage of the IAD method when applied to tissue optics is the possibility of rapidly obtaining iterative solutions with the aid of up-to-date microcomputers; moreover, it is flexible enough to take into account anisotropy of scattering and the internal reflection from the sample boundaries. The method includes the following steps: (i) the choice of optical parameters to be measured; (ii) counting reflections and transmissions; (iii) comparison of calculated and measured reflectance and transmittance; and (iv) repetition of the procedure until the estimated and measured values coincide with the desired accuracy.

The method allows any intended accuracy to be achieved for all the parameters being measured, provided the necessary computer time is available. An error of 3% or less is considered acceptable (Prahl, van Gemert and Welch, 1993). Also, the method may be used to directly correct experimental findings obtained with the aid of ISs. The term *doubling* in the method IAD means that the reflection and transmission estimates for a layer at certain ingoing and outgoing light angles may be used to calculate both the transmittance and reflectance for a layer twice as thick by means of superimposing one upon the other and summing the contributions of each layer to the total reflectance and transmittance. Reflection and transmission in a layer having an arbitrary thickness are calculated in consecutive order, first for the thin layer with the same optical characteristics (single scattering), then by consecutive doubling of the thickness, for any selected layer. The term *adding* indicates that the doubling procedure may be extended to heterogeneous layers for modeling multilayer tissues or taking into account internal reflections related to abrupt change in refractive index.

The IAD is a numerical method for solving the one-dimensional transport equation in slab geometry. It can be used for media with an arbitrary phase function and arbitrary angular distribution of the spatially uniform incident radiation. The IAD method has been successfully applied to determine optical parameters of blood; human and animal dermis; ocular tissues such as retina, choroids, sclera, conjunctiva, and ciliary body; aorta; and other soft tissues in the wide range of the wavelengths. The IAD provides accurate results in cases when the side losses are not significant, but it is less flexible than the IMC technique.

16.3.5
Inverse Monte Carlo Method

Both the real geometry of the experiment and the tissue structure may be complicated. Therefore, the MC method should be used if reliable estimates are to be obtained. A number of algorithms that use the IMC method are available now in the literature (see Tuchin, 2007).

Many researchers use the MC simulation program provided by Jacques.

The MC technique is employed as a method to solve the forward problem in the inverse algorithm for the determination of the optical properties of tissues. The MC method is based on the formalism of the RTT (see Eq. (16.8)), where the absorption coefficient is defined as a probability of a photon to be absorbed per unit length, and the scattering coefficient is defined as the probability of a photon to be scattered per unit length. Using these probabilities, a random sampling of photon trajectories is generated.

The basic algorithm for the generation of photon trajectories can be shortly described as follows (Tuchin, 2007). A photon described by three spatial coordinates and two angles (x, y, z, θ, ϕ) is assigned its weight $W = W_0$ and placed in its initial position, depending on the source characteristics. When an incident photon enters a scattering layer, it is allowed to travel a free path length, l. The l value depends on the particle concentration, ρ, and extinction cross section σ_{ext}. The free path length l is a random quantity that takes any positive values with the probability density $p(l)$:

$$p(l) = \rho\sigma_{\text{ext}} e^{-\rho\sigma_{\text{ext}} l} \tag{16.33}$$

The particular realization of the free path length l is dictated by the value of a random number ξ that is uniformly distributed over the interval [0, 1]:

$$\int_0^l p(l)dl = \xi \tag{16.34}$$

Substituting Eq. (16.33) into Eq. (16.34) yields the value l of the certain realization in the form

$$l = -\frac{1}{\rho\sigma_{\text{ext}}} \ln \xi \tag{16.35}$$

If the distance l is larger than the thickness of the scattering system, then this photon is detected as transmitted without any scattering. If, having passed the distance l, the photon remains within the scattering volume, then the possible events of photon-particle interaction (scattering or absorption) are randomly selected.

The direction of the photon's next movement is determined by the scattering phase function substituted as the probability density distribution. Several approximations for the scattering phase function of tissue and blood have been used in MC simulations. These include the two empirical phase functions widely used to approximate the scattering phase function of tissue and blood, Henyey–Greenstein phase function (HGPF) (see Eq. (16.13)) and the Gegenbauer kernel phase function (GKPF) (Barber and Hill, 1990), and theoretical Mie phase function (Bohren and Huffman, 1983).

When the photon reaches the boundary, part of its weight is transmitted according to the Fresnel equations. The amount transmitted through the boundary is added to the reflectance or transmittance. Since the refraction angle is determined by the Snell's law, the angular distribution of the outgoing light can be calculated. The photon with the remaining part of the weight is specularly reflected and continues its random walk.

When the photon's weight becomes lower than a predetermined minimal value, the photon can be terminated using "Russian roulette" procedure.

This procedure saves time, since it does not make sense to continue the random walk of the photon, which will not essentially contribute to the measured signal. On the other hand, it ensures that the energy balance is maintained throughout the simulation process.

The MC method has several advantages over the other methods because it may take into account mismatched medium-glass and glass–air interfaces, losses of light at the edges of the sample, any phase function of the medium, and the finite size and arbitrary angular distribution of the incident beam. If the collimated transmittance is measured, then the contribution of scattered light into the measured collimated signal can be accounted for. The only disadvantage of this method is the long time needed to ensure good statistical convergence, since it is a statistical approach. The standard deviation of a quantity (diffuse reflectance, transmittance, etc.) approximated by MC technique decreases proportionally to $1/\sqrt{N}$, where N is the total number of launched photons. It is worthy to note that stable operation of the algorithm was maintained by generation from 10^5 to 5×10^5 photons per iteration. Two to five iterations were usually necessary to estimate the optical parameters with approximately 2% accuracy.

16.3.6
Spatially Resolved Measurements

For many tissues, *in vivo* measurements are possible only in the geometry of the backscattering. The spatially resolved reflectance (SRR) $R(r_{\mathrm{sd}})$ is defined as the power of the backscattered light per unit of area detected by a receiver at the surface of the tissue at a distance r_{sd} from the source. $R(r_{\mathrm{sd}})$ depends on the optical properties of the sample, that is, the absorption coefficient μ_a, the scattering coefficient μ_s, and the phase function $p(\theta)$, the refractive index, and the numerical aperture (NA) of the receiving system (Kumar and Schmitt, 1997; Farrell and Patterson, 2001). The corresponding relation for the backscattering intensity as a function of a source and detector positions and optical parameters can be written on the basis of a diffusion approximation (see Eq. (16.24)).

For a semi-infinite medium and source and detector probes (e.g., optical fibers) separated by a distance r_{sd} and normally oriented to the sample surface, the reflecting flux is given by Kumar and Schmitt (1997)

$$R = \frac{z_0 A}{2\pi}\left[\frac{\mu_{\mathrm{eff}}}{r_{\mathrm{sd}}^2 + z_0^2} + \frac{1}{(r_{\mathrm{sd}}^2 + z_0^2)^{3/2}}\right] \times \exp\left[-\mu_{\mathrm{eff}}(r_{\mathrm{sd}}^2 + z_0^2)^{1/2}\right] \quad (16.36)$$

where $z_0 = K/\mu_s'$ is the extrapolation length, K is a dimensionless constant with a magnitude that depends on the anisotropy parameter of the scatterers and the reflection coefficient at the surface, A is the area of detector, μ_{eff} is defined by Eq. (16.16).

The measurement of the intensity of a back-reflected light from a tissue for different source–detector separations, r_{sd}, is the basis of the spatially resolved technique, which allows one to evaluate the absorption and the scattering coefficients using, for example, the analytical expressions (16.24) or (16.36), valid for highly scattering thick tissues.

When optical parameters of skin or mucosa are under investigation, the small source–detector separations should be used, where the diffusion approximation is not valid due to proximity to the tissue boundary. In that case, more sophisticated approximations of the RTT solution should be employed; in particular, a numerical solution of the inverse problem by the MC method is prospective. Such an SRR measurement can be implemented using multifiber probes with a number of fixed source–detector separations or using a CCD with a special optical system, allowing for the depth profiling of tissue optical properties if enough fibers or pixels are employed.

16.3.7
Optical Coherence Tomography

OCT is a newly developed modality that allows one to evaluate the scattering and absorption properties of tissue *in vivo* within the limits of an OCT penetration depth of 1–3 mm (see Tuchin, 2007). The use of OCT to measure the single-scattering coefficient of tissues μ_s has been described by Schmitt, Knüttel and Bonnar (1993). In its simplest form, this method assumes that backscattered light from a tissue decreases in the intensity according to

$$I_b \cong I_0 \exp[-2(\mu_a + \mu_s)z] \qquad (16.37)$$

where $(\mu_a + \mu_s)$ is the total attenuation coefficient and $2z$ is the round-trip distance of light backscattered at a depth z. For most tissues in the NIR, $\mu_a \ll \mu_s$; thus, μ_s can be estimated roughly as

$$\mu_s \cong \frac{1}{2}z \left\{ \ln \left[\frac{I_b(z)}{I_0} \right] \right\} \qquad (16.38)$$

or as the gradient of a graph $\ln[I_b(z)/I_0]$ versus z. Experimental data for tissue OCT images show that the logarithmically scaled average for multiple in-depth scans' backscattered intensity, $\ln[I_b(z)]$, decays exponentially; thus, by performing a linear regression on this curve, the scattering coefficient can be determined. More comprehensive algorithms accounting for multiple scattering effects and properties of a small-angle scattering phase function are available in the literature (Tuchin, 2007; Levitz *et al.*, 2004).

16.3.8
Measurement of the Scattering Phase Function

Direct measurement of the scattering phase function $p(\theta)$ is important for the choice of an adequate model for the tissue being examined. The scattering phase function is usually determined from goniophotometric measurements (GPMs) in relatively thin tissue samples (Jacques, Alte and Prahl, 1987). Measured scattering intensity angular dependence is approximated either by the HGPF (see Eq. (16.13)) or by a set of HGPFs, with each function characterizing the type of scatterers and specific contribution to the angular dependence (Marchesini *et al.*, 1989). In the limiting case of a two-component model of a medium containing large and small (compared with the wavelength) scatterers, the angular dependence is represented in the form of anisotropic and isotropic components. Other approximating functions are equally useful, for example, those obtained from the Rayleigh–Gans approximation, ensuing from the Mie theory, or a two-parameter GKPF (HGPF is a special simpler case of this phase function) (see Tuchin, 2002, 2007). Some of these types of approximations were used to find the dependence of the scattering anisotropy factor g for dermis and epidermis on the wavelengths in the range of 300–1300 nm, which proved to coincide fairly well with the empirical formula (van Gemert *et al.*, 1989),

$$g_e \sim g_d \sim 0.62 + \lambda \times 0.29 \times 10^{-3} \tag{16.39}$$

on the assumption of a 10% contribution of isotropic scattering (at least in the spectral range of 300–630 nm). The wavelength λ is given in nanometers.

16.3.9
Human Tissue Optical Properties Analysis

The above-discussed methods and techniques were successfully applied for estimation of optical properties of a wide number of tissues. Measurements done *in vitro, ex vivo,* and *in vivo* for human tissues are summarized in Table 16.1. It is clearly seen that attention was primarily focused on female breast and head/brain optical properties investigations because of great importance and perspectives of optical mammography and optical monitoring and treatment of mental diseases. Skin and underlying tissues are also well studied.

The most detailed *in vitro* investigations of normal and coagulated brain tissues (gray matter, white matter, cerebellum, pons, and thalamus), as well as of native tumor tissues (astrocytoma WHO grade II and meningioma), using single-IS spectral measurements in the spectral range from 360 to 1100 nm and IMC algorithm for data processing are described by Yaroslavsky *et al.* (2002). All brain tissues under study shared qualitatively similar dependencies of the optical properties on the wavelength. The scattering coefficient decreased and the anisotropy factor increased with the wavelength, which can be explained by the lowering of the contribution of Rayleigh scattering and growing of the contribution of Mie scattering with the wavelength. The wavelength-dependent absorption coefficient behavior of all brain tissues resembled a mixture of oxy and deoxyhemoglobin absorption spectra. This means that in spite of careful preparation of the samples, it was not possible to remove all blood residuals from the tissue sections.

At the same time, the differences in the spectral characteristics of the brain tissues have been observed. For example, the total attenuation coefficients ($\mu_t = \mu_a + \mu_s$) of white matter are substantially higher than those of gray matter. The two brain stem tissues (pons and thalamus) also have different optical properties. The tumors are generally macroscopically less homogeneous than any normal tissues; thus, their scattering coefficients and anisotropy factors are slightly higher than those of normal gray matter. The same tendency of scattering coefficients growing is typical for breast tumors (carcinomas) (Peters *et al.*, 1990).

After coagulation, the values of absorption and scattering coefficients increased for all tissues. The extent of this increase, however, is different for each tissue type, and is characterized by factors from 2 to 5. It was shown (Yaroslavsky *et al.*, 2002) that a significant increase of both interaction coefficients is a result of substantial structure changes, caused mostly by tissue shrinkage and condensation, as well as collagen swelling and homogenization of the tissue. Tissue shrinkage caused by losing water at coagulation makes tissue more dense, which leads to increase of both scattering and absorption coefficients in the spectral range

where water absorption is weak (up to 1100–1300 nm). The refractive index microscopic redistribution of a tissue due to cellular and fiber proteins' denaturation and homogenization at thermal action also may have a strong inclusion in alteration of scattering and absorption properties.

16.3.10
Optical Properties of Blood

Fresh human blood placed in calibrated thin cuvette (thickness from 0.01 to 0.5 mm, slab geometry) is usually used for the determination of blood optical parameters. Before the optical measurements, standard clinical tests are necessary to determine the concentration of red and white blood cells, concentration of platelets, hematocrit, mean corpuscular volume and hemoglobin, and the other parameters of interest. If blood sample oxygenation level is of interest, it may be controlled using a conventional blood gas analyzer (Yaroslavsky *et al.*, 1999). In most cases, the experiments are performed with either completely oxygenated or completely deoxygenated blood (Hammer *et al.*, 1998; Roggan *et al.*, 1999; Yaroslavsky *et al.*, 1999; Tuchin, 2002). To obtain complete oxygen saturation, the sample is exposed to air or O_2. To completely deoxygenate blood, sodium dithionite ($Na_2S_2O_4$) is added. To be sure that neither the volume nor the surface area of the blood particles changes during the experiments, the pH of the samples should be maintained in the range of physiological values, at approximately 7.4.

In reality, blood is flowing through the blood vessels and, therefore, it is preferable to study the optical properties of flowing blood. The red blood cells (RBCs) in flow are subject to deformation and orientation. At lower shear rates, reversible aggregation occurs; while under the higher shear rates, erythrocytes are deformed into ellipsoids. The experiments with flowing undiluted and diluted blood are reported (Nilsson *et al.*, 1997; Roggan *et al.*, 1999; Steenbergen, Kolkman and de Mul, 1999).

16.3.11
Refractive Index Measurements

Refractivity measurements in a number of strongly scattering tissues and blood were performed using various techniques (see Tuchin, 2007). Experimental values of mean refractive index for some tissues measured for selected wavelengths are summarized by Tuchin (2007). One of the techniques is a fiber-optic refractometer based on a simple concept that the cone of light issuing from an optical fiber is dependent on the indices of the cladding material (tissue) (Bolin *et al.*, 1989). Using this simple and sensitive technique, it was found that at 633 nm, fatty tissue has the largest refractive index (1.455), followed by kidney (1.418), muscular tissue (1.410), then blood and spleen (1.400). The lowest refractive indices were found in lungs and liver (1.380 and 1.368, respectively). Also, it turned out that tissue homogenization does not significantly affect the refractive indices (the change does not exceed a measurement error equal to 0.006), whereas coagulated tissues have higher refractive indices than native ones (e.g., for egg white, $\overline{n}$ changing from 1.321 to 1.388). Moreover, there is a tendency for refractive indices to decrease with increasing light wavelength from 390 to 700 nm (e.g., for bovine muscle in the limits 1.42–1.39), which is characteristic of the majority of related abiological materials.

The principle of total internal reflection at laser beam irradiation is also used for tissue and blood refraction measurements (Liu and Xie, 1996; Cheng *et al.*, 2002). A thin tissue sample is sandwiched between two right-angled prisms that are made of ZF5 glass with a high refractive index $n_0 = 1.70827$ and angle $\alpha = 29^0 55' 41.4''$. Measurements for fresh animal tissues and human blood at four laser wavelengths 488, 632.8, 1079.5, and 1341.4 nm and room temperature were presented in a form of Cauchy dispersion equation as (Cheng *et al.*, 2002)

$$\overline{n} = A + B\lambda^{-2} + C\lambda^{-4} \qquad (16.40)$$

with λ in nanometers, values of the Cauchy coefficients are given in the following table (Table 16.2):

An expression for human blood plasma received by Cheng *et al.* (2002) was extrapolated to shorter wavelengths from 400 to 1000 nm (Tuchin *et al.*, 2004):

$$\begin{aligned} n_{\text{bp}}(\lambda) = {} & 1.3254 + 8.4052 \times 10^3 \lambda^{-2} \\ & - 3.9572 \times 10^8 \lambda^{-4} \\ & - 2.3617 \times 10^{13} \lambda^{-6} \qquad (16.41) \end{aligned}$$

For modeling of the behavior of refractive index of tissues, blood, and their components, one may use a remarkable property of proteins: that equal concentrations of aqueous solutions of different proteins all have approximately the same refractive index, n_{pw} (Barer, Ross and Tkaczyk, 1953). Moreover, the refractive index varies almost linearly with concentration, C_p

$$n_{\text{pw}}(\lambda) = n_w(\lambda) + \beta_p(\lambda) \cdot C_p \qquad (16.42)$$

where n_w is refractive index of water and β_p is the specific refractive increment; C_p is measured in grams per 100 ml (grams per deciliter). For example, the refractive index of human erythrocyte cytoplasm, defined by the cell-bounded hemoglobin solution, can be found from this equation at $\beta_p = 0.001942$ valid for a wavelength of 589 nm; that is, for normal hemoglobin concentration in cytoplasm of 300–360 g l^{-1}, the RBC refractive index $n_{\text{RBC}} = 1.393$–1.406 (Roggan *et al.*, 1999). Values of specific refractive increment β_p for some other proteins measured by Abbe refractometer at a wavelength 589 nm are given in the following table (Table 16.3) (Barer, Ross and Tkaczyk, 1953):

Other materials of specific biological interest are the carbohydrates, lipoids, and nucleic acid compounds. The first two usually have low values of β; in

Tab. 16.2 Values of the Cauchy coefficients for some tissues.

$^{\perp}$ Same sample with the tissue fibers oriented perpendicular to the interface.

Tab. 16.3 Values of specific refractive increment β_p for some proteins measured by Abbe refractometer at a wavelength 589 nm.

Protein	β_p**, dl/g**
Lipoprotein	0.00170–0.00171
Total serum (human)	0.00179
Total albumin	0.00181
Egg albumin	0.001813
Euglobulin	0.00183

the region of 0.0014–0.0015, and nucleic acids have higher values, 0.0016–0.0020 (Barer, Ross and Tkaczyk, 1953).

Some other techniques of refractive index measurements of biological liquids are also available. One of them allows for refractive index measurements at a few separate wavelengths and uses an equilateral small angle (of 10°) hollow prism made from thin quartz slides (Sardar and Levy, 1998).

Since the refractive index of tissue and blood components defines their scattering properties, measured scattering parameters may have an advantage to evaluate the refractive index of biomaterial components and their mean values (Tuchin, 2007). Determination of the reduced scattering coefficient of a tissue sample using IS or spatially resolved techniques and corresponding algorithms for extraction of the scattering coefficient, such as IAD or IMC, the knowledge of the refractive indices of the scatterers and the ground material at one of the wavelengths, as well as experimental or theoretical estimations for mean radius of the scatterers, allows one to solve the inverse problem and reconstruct the spectral dependence of the refractive index of the scatterers for a given spectral dependence of the refractive index of the ground material. Similar measurements and theoretical estimations done for a tissue sample before and after its prolonged bathing in saline or other biocompatible liquid with known optical characteristics allow one to evaluate the spectral dependencies both of refractive index of the scatterers and the ground material.

A short pulse time delay technique was also successfully applied for refractive index estimation of normal breast tissue and malignant breast tissue (Das, Liu and Alfano, 1997). Using the known thickness of the sample and the measured shift Δt of the transmitted pulse peak relative to the delay time measured through a layer of air of the same thickness, the mean phase refractive index $\overline{n}$ of a tissue sample can be calculated. Very short pulses should be used in such measurements; thus, a group of different wavelengths propagates in a media and the material dispersion $(d\overline{n}/d\lambda)$ should be accounted for by introducing the group refractive index

$$\overline{n}_g = \overline{n} - \lambda \frac{d\overline{n}}{d\lambda} \tag{16.43}$$

The time delay in the pulse arrival for a tissue sample of thickness d is

$$\Delta t = \frac{d}{c_0}(\overline{n}_{g1} - n_{g2}) \tag{16.44}$$

where c_0 is the light velocity in a free space; $\overline{n}_{g1}$ is the effective (mean) group refractive index of a tissue, and n_{g2} is the group refractive index of the homogeneous reference medium (air). The effective group refractive index of a tissue is

$$\overline{n}_{g1} = f_s n_{gs} + (1 - f_s) n_{g0} \tag{16.45}$$

where f_s is the volume fraction of the scatterers composing a tissue, n_{gs} is the group refractive index of the scatterers, and n_{g0} is the group refractive index of the ground material of a tissue. The values of the phase refractive index of the above-mentioned two samples were calculated to be $\overline{n} = 1.403$ for normal and 1.431 for malignant tissue.

OCT provides simple and straightforward measurements of the index of refraction both *in vitro* and *in vivo* (Tearney *et al.*, 1995; Wang *et al.*, 1995; Knüttel and Boehlau-Godau, 2000; Knüttel, Bonev and Knaak, 2004; Ohmi *et al.*, 2000; Tuchin, Xu and Wang, 2002; Tuchin, 2007). The in-depth scale of OCT images is determined by the optical path length Δz_{opt} between two points along the depth direction. Because a broadband light source is used, the optical path length is proportional to the group refractive index n_g and geometrical path length Δz as

$$\Delta z_{\text{opt}} = n_g \Delta z \tag{16.46}$$

Usually, $n_g \cong n$. This simple relation is valid for a homogeneous medium and can be used in *in vitro* studies when geometrical thickness of a tissue sample Δz is known.

Sometimes both refractive index and thickness of a tissue sample should be measured simultaneously. In that case, a two-step procedure can be applied. First, a stationary mirror is placed in the sample arm of an interferometer to get the geometric position of the mirror supposing that the group refractive index of air is 1 (z_1). Then a tissue sample with unknown index n_g, and thickness d should be placed before the mirror in the sample arm. Two peaks from the anterior (z_2) and the posterior (z_3) surfaces of the sample will appear with the distance between them equal to a sample optical thickness, and the position of the mirror (z_4) will be shifted by $(n_g - 1)d$ due to the sample whose group refractive index is greater than that of air. Thus, the calculation of the geometrical thickness and the group refractive index proceeds as follows:

$$\begin{aligned} d &= (z_3 - z_2) - (z_4 - z_1) \\ n_g &= \frac{z_3 - z_2}{d} \end{aligned} \tag{16.47}$$

For *in vivo* measurements of the index of refraction, a focus-tracking method that uses OCT to track the focal-length shift that results from translating the focus of an objective along the optical axis within a tissue was introduced (Tearney *et al.*, 1995) and further developed (Knüttel and Boehlau-Godau, 2000; Knüttel, Bonev and Knaak, 2004; Zvyagin *et al.*, 2003).

16.3.12
Optical Projection Tomography

Optical projection tomography (OPT), based on ballistic and/or quasi-ballistic photon detection, allows for imaging inhomogeneities and quantifying optical properties of biological materials with thicknesses from tens of microns to centimeters (Darrell *et al.*, 2008; Oldham *et al.*, 2008). Major applications are in developmental embryology and gene expression studies, as well as in three-dimensional imaging and quantification within organs of small animals and xenograft tumors. Typically, light from a uniform backlight transverses through the sample to form projection images captured by a CCD camera or fluorescence from fluorophores distributed in biological material and excited by a light orthogonal to the imaging axis is detected at rotation of the sample around its axis. There have been substantial developments in modeling, reconstructing algorithms, reflection, refraction and scattering reduction, and in enhancements of the optical systems used in OPT. As it was noted by Darell *et al.* (2008), several applications of OPT would benefit from quantitative reconstructions, that is, reconstructions in which, for example, the intensities of two areas of gene expression could be reliably compared, thus, they described methods of accounting for the quantitative effects of the isotropic emission and blurring in a fluorescence OPT imaging system.

Glossary

Absorption Coefficient: In a nonscattering medium absorption coefficient μ_a is defined as the reciprocal of the distance d over which light of intensity $I(d = 0) = I_0$ is attenuated (due to absorption) to $I(d) = I_0/e \approx 0.37 I_0$; the units are typically cm^{-1}; behind this definition is a fundamental process of photon absorption that is characterized by a photon absorption cross section.

Anisotropic Scattering: A scattering process characterized by a clearly apparent direction of photons that may be due to the presence of large scatterers.

Aorta: The great artery that leaves the left ventricle; it conducts the whole of the arterial blood supply to all parts of the body other than the lungs; in humans, it carries blood at the rate of 4 dm^3 per minute.

Astrocytoma: A rather well-differentiated glioma (a *tumor* of the brain), which consists of cells that look like astrocytes (a starlike cell of the macroglia of nerve tissue).

Bilirubin: Yellow bile pigment formed in the breakdown of heme (an iron-containing substance; the basic unit of the *hemoglobin* molecule; mammals have four heme units in their hemoglobin).

Cancer: A general term applied to a carcinoma or a sarcoma; the typical symptoms are a *tumor* or swelling, a discharge, pain, an upset in the function of an organ, general weakness, and loss of weight.

Cartilage: A strong, resilient, skeletal tissue; its simplest and most common form consists of a matrix of a polysaccharide-containing protein in which are embedded cartilage cells (chondroblasts); the matrix is without structure and without blood vessels; this type is known as *hyaline cartilage*, is translucent and clear, and occurs in the cartilaginous rings of the trachea and bronchi; elastic cartilage (yellow fibrocartilage) contains yellow fibers in the matrix; it occurs in the external ear and in the epiglottis; white fibrocartilage contains white fibers in the matrix; it occurs in the disks of cartilage between the vertebrae; all types of cartilage contain chondroblasts, which deposit the matrix and become enclosed in the matrix as chondrocytes.

CCD: Charge-coupled device – a solid-state electronic device that serves as an imaging chip and is used in video cameras and fast spectrometers.

Cell Organelle: A part of a cell that is a structural and functional unit, for example, a flagellum is a locomotive organelle, a *mitochondrion* is a respiratory organelle; organelles in a cell correspond to organs in an organism.

Cerebellum: A region of the brain that plays an important role in the integration of sensory perception and motor output; many neural pathways link the cerebellum with the motor cortex, which sends information to the muscles causing them to move and the spinocerebellar tract that provides feedback on the position of the body in space; the cerebellum integrates these pathways, using the constant feedback on body position to fine-tune motor movements.

Cerebral Membrane (*dura mater*): Or pachymeninx, is the tough and inflexible outermost of the three layers of the *meninges* surrounding the brain and spinal cord; the *dura mater* itself has two layers: a superficial layer, which is actually the skull's inner *periosteum*, and a deep layer, the *dura mater proper*.

Collagen: A tough, inelastic, fibrous protein; on boiling it forms gelatin; on adding acetic acid it swells up and dissolves; collagen is formed and maintained in tissues by fibroblasts; it forms white fibers in *connective tissue*; the tropocollagen or "collagen molecule" subunit is a rod about 300-nm long and 1.5 nm in diameter, made up of three polypeptide strands, subunits spontaneously self-assemble, with regularly staggered ends, into even larger arrays in the extracellular spaces of tissues; there is some covalent crosslinking within the triple helices, and a variable amount of covalent crosslinking between tropocollagen helices, to form the different types of collagen found in different mature tissues – similar to the situation found with the α-keratins in hair; a distinctive feature of collagen is the regular arrangement of amino acids in each of the three chains of these collagen subunits; in bone, entire collagen triple helices lie in a parallel, staggered array; 40-nm gaps between the ends of the tropocollagen subunits probably serve as nucleation sites for the deposition of long, hard, fine crystals of the mineral component, which is (approximately) hydroxyapatite with some phosphate; it is in this way that certain kinds of cartilage turn into bone; collagen gives bone its elasticity and contributes to fracture resistance.

Connective Tissue: Various body tissues that bind together and support organs and other tissues, for example, connective tissue surrounds muscles and nerves, connects bones and muscles and underlies the *skin; cartilage* and bone are also connective tissues; typical connective tissue consists of cells scattered in an amorphous mucopolysaccharide matrix in which there are varying amounts of connective tissue fibers (mainly *collagen*, but also *elastin* and *reticulin*)

CW: Continuous wave

Cytoplasm: All the protoplasm of a cell exclusive of the nucleus; it is not just a simple, slightly viscous, fluid; various structures, called *organelles*, each concerned with different functions of the cell, are situated in it; the plasma membrane is part of the cytoplasm.

Cytoplasmic Organelles: See *cell organelle*.

Dermis: The inner layer of the *skin*; it is composed of *connective tissue*, blood and lymph vessels, muscles and nerves; *collagen* fibers are abundant in the dermis and run parallel to the surface of the skin; they give the skin elasticity; sweat glands and hair follicles are scattered throughout the dermis; the dermis is much thicker than the epidermis and is developed from mesoderm.

Diffusion Approximation (Diffusion Theory): The approximated diffusion-type solution of the *RTT*, which is accurate for describing of photon migration in infinite, homogeneous, highly scattering media.

Dysplasia: An abnormality in the appearance of cells indicative of an early step toward transformation into a neoplasia. It is therefore a preneoplastic or precancerous change; this abnormal growth is restricted to the originating system or location, for example, a displasia in the epithelial layer will not invade into the deeper tissue, or a displasia solely in a red blood cell line (refractory anemia) will stay within the bone marrow and cardiovascular systems; the best known form of displasia is the precursor lesions to cervical *cancer*, called cervical intraepithelial neoplasia (CIN); this lesion is usually caused by an infection with the human papilloma virus (HPV).

Elastin: An elastic fibrous protein resistant to boiling and to acetic acid; it forms highly elastic yellow fibers in *connective tissue*; elastin is formed and maintained in tissues by fibroblasts.

Epidermis: The outer layer of the *skin* is a stratified *epithelium* that varies relatively little in thickness over most of the body (between 75 and 150 μm), except on the palms and soles, where its thickness may be 0.4–0.6 mm; the epidermis is conventionally subdivided into (i) stratum basale, a basal cell layer of keratinocytes, which is the germinative layer of the epidermis; (ii) the stratum spinosum, which consists of several layers of polyhedral cells lying above the germinal layer; (iii) the stratum granulosum, which is a layer of flattened cells containing distinctive cytoplasmic inclusions and keratohyalin granules; and (iv) the overlying *stratum corneum*, consisting of lamellae of anucleate thin, flat squames that are terminally differentiated keratinocytes.

Epithelium: A sheet of epithelial tissue; epithelium is derived from ectoderm and endoderm.

Eye Cornea: The transparent covering at the front of the eyeball; it is the modified continuation of the *sclera*; it refracts light and is the most important element in the refractive system of the eye.

Eye Sclera: A dense, white matter, fibrous membrane which, with the *cornea*, forms the external covering of the eyeball; scleral regions: limbal, equatorial, and posterior pole region.

Extinction Coefficient (Attenuation Coefficient): The reciprocal of the distance over which light of intensity I is attenuated to $I/e \approx 0.37I$; attenuation or interaction coefficient, $\mu_t = \mu_a + \mu_s$, where μ_a is the *absorption coefficient* and μ_s is the *scattering coefficient*; the units are typically cm^{-1}.

***Ex vivo*:** Taken from the living organism; pertaining to experiments on animal or human organs that are excised from the living body and kept in conditions very close to the natural ones.

Fat (Adipose Tissue): A modification of areolar *tissue* in which globules of oil are deposited in some of the cells (fat cells); the cells tend to be grouped together and in mammals occur in the tissues under the skin and around the abdominal organs (kidneys, liver, etc.).

Fibrous Tissue: A tissue mainly consisting of conjunctive *collagen* (or *elastin*) fibers, often packed in lamellar bundles.

GKPF: Gegenbauer kernel phase function.

Golgi Apparatus: A netlike mass of material in the *cytoplasm* of animal cells, believed to function in cellular secretion.

Gray Matter: A nervous tissue found in the central nervous system; it contains numerous cell bodies (cytons), dendrites, synapses, terminal processes of axons, blood vessels, and neuroglia; it is internal to *white matter* in the spinal cord and some other parts of the brain; it is external to white matter in the cerebral hemisphere and in the *cerebellum*; coordination in the central nervous system is effected in gray matter; brain nuclei and nerve centers are composed of gray matter.

Hemoglobin: A red iron-containing respiratory pigment found in the blood; it conveys oxygen to the tissues and occurs in reduced form (deoxyhemoglobin) in venous blood and in combination with oxygen (oxyhemoglobin) in arterial blood; it consists of *heme* combined with globin, a blood protein; it is chemically related to chlorophyll, cytochrome, hemocyanin, and myoglobin.

HGPF: Henyey–Greenstein phase function.

Horny Layer: The same as stratum corneum, see *epidermis*.

Interstitial Fluid: A solution that bathes and surrounds the cells of multicellular animals; it is the main component of the extracellular fluid, which also includes plasma and transcellular fluid; on average, a subject has about 11 l of interstitial fluid providing the cells of the body with nutrients and a means of waste removal.

IAD: Inverse adding-doubling.

IMC: Inverse Monte Carlo.

In vitro: In medicine, pertaining to experiments on dead tissue.

In vivo: In medicine, pertaining to experiments on living animals and humans.

Isotropic Scattering: An equality of scattering properties along all axes.

Lysosomes: Membrane-bound particles, smaller than a *mitochondrion*, occurring in large numbers in the *cytoplasm* of cells; they contain hydrolytic enzymes that are released when the cell is damaged; these enzymes assist in the digestion and removal of dead cells, the digestion of food and other substances, and the destruction of redundant *organelles*.

Melanin: A dark-brown or black pigment; melanin in *melanosomes* of normal *skin* is an extremely dense, virtually insoluble polymer of high molecular weight and is always attached to a structural protein; mammalian melanin pigments have one of two chemical compositions: eumelanin, a brown polymer, and pheomelanin, a yellow–reddish alkali-soluble pigment.

Melanosome (Melanin Granular): The cytoplasmic **organelles** on which melanin pigments are synthesized and deposited; normal human skin color is primarily related to the size, type, color, and distribution of melanosomes; melanosomes are the product of specialized exocrine glands: melanocytes.

Meningioma: The most common benign *tumor* of the brain (95% of benign tumors); however, they can also be malignant; they arise from the arachnoidal cap cells of the meninges and represent about 15% of all primary brain tumors; they are more common in females than in males (2 : 1) and has a peak incidence in the sixth and seventh decades.

Mesentry: Sheets of thin **connective** *tissue* by which the stomach and intestines are suspended from the dorsal wall of the abdominal cavity; the mesenteries carry blood, lymph vessels, and nerves to the organs of the alimentary canal.

Mitochondrion (*pl.* Mitochondria): A threadlike, or rodlike, granular *organelle* in the *cytoplasm* of cells, about 0.5 μm in width, and up to 10 μm in length for threadlike mitochondria; mitochondria are bounded by a double membrane; the inner membrane is folded inward at a number of places to form cristae; mitochondria contain phosphates and numerous enzymes that vary in different tissues; their function is cellular respiration and the release of chemical energy in the form of adenosine triphosphate (ATP) for use in most of the cell's biological functions; the cells of all organisms, except bacteria and blue–green algae, contain mitochondria in varying numbers mitochondria are especially numerous in cells involved in significant metabolic activity, such as **liver** cells; mitochondria are self-replicating.

MFP: Mean free path of a photon.

Myocardium: The muscular substance of the heart.

OCT: Optical coherence tomography.

Percutaneous: Pertains to any medical procedure where access to inner organs or other tissue is done through the *skin*, for instance, via needle puncture of the skin, rather than by using an "open" approach where inner organs or tissue are exposed; phototherapy is another example of percutaneous treatment.

Peroxisome: A specialized *organelle* containing the oxidizing enzymes that degrade peroxides.

Photon Diffusion Coefficient: The proportionality coefficient between mean-square displacement of a photon within time interval τ: $\langle \Delta r^2 \rangle \sim D\tau$.

Pons: A structure located on the brain stem; in humans it is above the medulla, below the midbrain, and anterior to the *cerebellum*.

Reduced (Transport) Scattering Coefficient: A lumped property incorporating the *scattering coefficient* μ_s and the *scattering anisotropy parameter* g: $\mu_s{}' = \mu_s(1-g)$ (cm^{-1}); $\mu_s{}'$ describes the diffusion of photons in a random walk of step size of $1/\mu_s{}'$ (cm), where each step involves isotropic scattering; this is equivalent to description of photon movement using many small steps $1/\mu_s$ that each involve only a partial (anisotropic) deflection angle if there are many scattering events before an absorption event, that is, $\mu_a \ll \mu_s'$ (diffusion regime, see *diffusion approximation*); μ_s' is useful in the diffusion regime, which is commonly encountered when treating how visible and near-infrared light propagates through tissues; for many *tissues*, the reduced scattering coefficient obeys a power law, $\mu_s{}' = q\lambda^{-h}$(cm^{-1}, λ in μm).

Ribosomes: In the *cytoplasm* of a cell any several minute, angular, or spherical particles composed of protein and RNA.

RTT: Radiation transfer theory.

Scattering Anisotropy Parameter: A measure of the amount of forward direction retained after a single scattering event; if a photon is scattered by a particle so that its trajectory is deflected by a deflection angle θ, then the component of the new trajectory that is aligned in the forward direction is presented as $\cos\theta$; there is an average deflection angle and the mean value of $\langle\cos\theta\rangle$ is defined as the anisotropy, $g \equiv \langle\cos\theta\rangle$; the value of g varies in the range from -1 to 1: $g = 0$ corresponds to isotropic (Rayleigh) scattering, $g = 1$ to total forward scattering (Mie scattering at large particles), and -1 to total backward scattering.

Scattering Coefficient: A particle with a particular geometrical size redirects incident photons into new directions and so prevents the forward on-axis transmission of photons, this process constitutes scattering; the scattering coefficient μ_s (cm^{-1}) describes a medium containing many scattering particles at a concentration described as a volume density ρ (cm^3); the scattering coefficient is essentially the cross-sectional area σ_{sca} (cm^{-1}) per unit volume of medium: $\mu_s = \rho\sigma_{\text{sca}}$; a power law for dependence of the scattering coefficient on the wavelength is typical for many tissues: $\mu_s \propto \lambda^{-h}$, for different tissue structures parameter h is ranging from 1 to 2.

Scattering Phase Function: The function that describes the scattering properties of the medium and is, in fact, the probability density function for scattering in the direction $\bar{s}'$ of a photon traveling in the direction $\bar{s}$; it characterizes an elementary scattering act: if scattering is symmetric relative to the direction of the incident wave, then the phase function depends only on the scattering angle θ (angle between directions $\bar{s}$ and $\bar{s}'$).

Skin: The external protective covering on a body, joined by *connective tissue* to the muscles; it consists of an inner *dermi*s and an outer *epidermis*.

Stratum Corneum: see *epidermis stroma* The supporting framework, usually of *connective tissue*, of an organ, as distinguished from the parenchyma, for example, the main layer of the *eye sclera* and *cornea*.

Tendon: A cord of white *fibrous tissue*; it usually attaches muscle to bones.

Thalamus: A pair and symmetric part of the brain; it constitutes the main part of the diencephalons; in the caudal (tail) to oral (mouth) sequence of neuromeres, the diencephalons is located between the mesencephalon (cerebral peduncule, belonging to the brain stem) and the telencephalon.

TMFP: Transport mean free path of a photon.

Tumor: An abnormal or diseased swelling in any part of the body, especially a more or less circumscribed overgrowth of new *tissue* that is autonomous, differs more or less in structure from the part in which it grows, and serves no useful purpose; neoplasm.

White Matter: The nervous *tissue* found in the central nervous system; it consists of tracts of medullated nerve fibers in the brain and spinal cord; it also contains blood vessels and neuroglia; it is mainly external to *gray matter*, but is internal to gray matter in the cerebral hemispheres and in the *cerebellum*; the medullated fibers give the tissue its shiny white appearance.

WHO: World Health Organization.

Whole Blood: Blood containing all its natural components: blood cells and plasma.

17.1
Introduction

The first detection of the fluorescence light of a single molecule dates back to 1976 (Hirschfeld, 1976). At that time, the molecule under investigation contained about 100 fluorescent chromophores. With the advent of extremely sensitive photon detectors and effective filters, the detection of the fluorescence of just a single fluorophore became possible in 1990 (Orrit and Bernard, 1990), however, in a crystalline host at liquid helium temperature. In the same year, single fluorophores were observed in solution at room temperature (Shera *et al.*, 1990), paving the way to the application of single-molecule fluorescence on biological systems in their native surrounding. The next milestones for the perception of single-molecule fluorescence as a useful biophysical technique were the demonstration of fluorescent resonance energy transfer on an individual basis (Ha *et al.*, 1996) and the direct observation of the diffusion of a dye-labeled protein in a lipid bilayer (Schmidt *et al.*, 1995). These two key experiments sparked a tremendous development of the technique over the following years, and already in 2001 the coming of age of single-molecule spectroscopy was stated (Kelley, Michalet and Weiss, 2001). Today, the number of groups performing single-molecule fluorescence detection as well as the number of publications in the field is rapidly growing. The pioneers of single-molecule fluorescence have set out their children, and the grand children are starting their own groups. This chapter therefore cannot be comprehensive, but rather a selection of prototype experiments demonstrating the enormous potential of single-molecule fluorescence for molecular protein biophysics, with an emphasis on protein conformation in the context of protein folding and catalysis. Owing to space limitations, the fields of single-molecule observations of molecular motors and of membrane diffusion are omitted.

Thereby, the aspects of the respective applications will be balanced by the methodological developments. The aim of this approach is to provide the reader with a framework of knowledge that allows for deciding whether a single-molecule approach to a certain problem might be advantageous, and which method is to be preferred.

The basic photophysical principles underlying fluorescence detection, particularly at the high excitation rates necessary

to observe the faint light of a single dye molecule, are outlined in the second section. The third section briefly introduce the experimental layouts used, emphasizing their advantages and drawbacks. Finally, selected applications are discussed in the fourth section.

17.2
Photophysical Basics

17.2.1
Energy Levels and Transitions

The fluorescence of single dye molecules is based on the same energy level scheme as ordinary molecular bulk fluorescence, consisting of, in the simplest case, an electronic ground state, an excited state, and a triplet state. In each electronic level, several vibronic states exist. The high repetition rates needed to obtain a measurable signal, however, demand a second look at the energy levels and transitions involved. Besides the levels found in every textbook, higher excited states are shown in the Jablonski diagram in Figure 17.1. Those higher levels exist both in the singlet as well as in the triplet manifold. At high laser intensities, in particular in pulsed excitation, further excitations from the states S_1 and T_1 are possible.

First taking only transitions between the electronic ground state S_0, the first excited singlet state S_1, and the first excited triplet state T_1 into account and neglecting stimulated emission, the following set of rate equations can be derived:

$$\begin{aligned}\dot{n}_1 &= -I\sigma n_1 + k_{\text{rad}} n_2 \\ &\quad + k_{\text{ic}} n_2 + k_{\text{risc}} n_3 \\ \dot{n}_2 &= I\sigma n_1 - k_{\text{rad}} n_2 - k_{\text{ic}} n_2 - k_{\text{isc}} n_2 \\ \dot{n}_3 &= k_{\text{isc}} n_2 - k_{\text{risc}} n_3 \end{aligned} \tag{17.1}$$

where n_1, n_2, and n_3 are the occupation probabilities of S_0, S_1, and T_1, respectively, k_{rad} the radiative rate, k_{ic} the rate of internal conversion, k_{isc} the intersystem crossing rate, k_{risc} the reverse intersystem crossing rate, I the excitation intensity, and σ the absorption cross section of the fluorophore.

The quantum yield of fluorescence Φ_f is the ratio of radiative transitions from

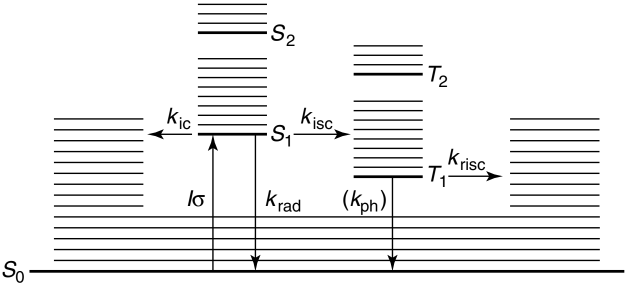

Fig. 17.1 Jablonski diagram showing the electronic ground state S_0, the first electronically and second excited singlet states S_1 and S_2, the first and the second electronically excited triplet states T_1 and T_2, and the most important transitions between the states as detailed in the text.

S_0 to all other transitions from that state:

$$\Phi_f = \frac{k_{\mathrm{rad}}}{k_{\mathrm{ic}} + k_{\mathrm{isc}} + k_{\mathrm{rad}}} = k_{\mathrm{rad}}\tau_f \qquad (17.2)$$

where τ_f is the fluorescence lifetime, which is the experimentally accessible time constant of the decay of fluorescence after pulsed excitation. Therefore, the quantum yield of fluorescence can be determined by measuring the fluorescence lifetime and deriving k_{rad} from the absorption and emission spectra of the dye making use of the relation between the Einstein coefficients for absorption and spontaneous emission (Strickler and Berg, 1962):

$$k_{\mathrm{rad}} = 2.88 \times 10^{-9} n^2 \frac{\int F(\bar{\nu})d\bar{\nu}}{\int F(\bar{\nu})d\bar{\nu}/\bar{\nu}^3} \times \int \frac{\varepsilon(\bar{\nu})}{\bar{\nu}} d\bar{\nu} \qquad (17.3)$$

where $F(\bar{\nu})$ is the fluorescence and $\varepsilon(\bar{\nu})$ the absorption spectrum of the dye, with $\bar{\nu}$ the wave number in cm^{-1}. Fluorophores for single-molecule spectroscopy should have quantum yields of fluorescence close to unity to ensure a strong enough fluorescence signal to be detected. Therefore, the intersystem crossing rate as well as the rate of internal conversion should be small.

Under stationary conditions (all time derivatives are zero), the emission rate R as a function of the excitation rate from the set of rate equations (17.1) is given by

$$R = n_2 k_{\mathrm{rad}} = \frac{k_{\mathrm{rad}}}{1 + \frac{k_{\mathrm{isc}}}{k_{\mathrm{risc}}} + \frac{k_{\mathrm{rad}} + k_{\mathrm{ic}} + k_{\mathrm{ies}}}{I\sigma}} \qquad (17.4)$$

Owing to increasing population of the triplet state T_1 at high excitation rates, the maximum achievable emission rate with infinitely strong excitation is R_∞:

$$R_\infty = \frac{k_{\mathrm{rad}}}{1 + \frac{k_{\mathrm{isc}}}{k_{\mathrm{risc}}}} \qquad (17.5)$$

The emission rate R can be rewritten as

$$R = R_\infty \frac{1}{\left(1 + \frac{I_{\mathrm{sat}}}{I}\right)} \qquad (17.6)$$

with the saturation intensity I_{sat}, which is the excitation intensity where half of the maximum emission rate is reached, given by

$$I_{sat} = \frac{k_{\mathrm{risc}}}{\sigma} \frac{k_{\mathrm{rad}} + k_{\mathrm{ic}} + k_{\mathrm{isc}}}{k_{\mathrm{risc}} + k_{\mathrm{isc}}} \qquad (17.7)$$

The saturation of the average emission rate due to triplet excursions is known as the *triplet bottleneck*.

The solution to the set of rate equations 17.1 with the initial condition of $n_1 = 1$, $n_2 = n_3 = 0$ provides the time evolution of the occupation probability of the first electronically excited singlet state $n_2(t)$, which is related to the fluorescence intensity autocorrelation function or second-order autocorrelation function $g^{(2)}(t)$ defined as

$$g^{(2)}(t) = \frac{\langle n(\tau)n(t+\tau)\rangle_\tau}{\langle n(\tau)\rangle_\tau^2} = \frac{n_2(t)}{\langle n_2\rangle} \qquad (17.8)$$

and reads

$$g^{(2)}(t) = 1 - \frac{k_{\mathrm{isc}}^{\mathrm{eff}} + k_{\mathrm{risc}}}{k_{\mathrm{risc}}} e^{-(k_{\mathrm{rad}}+2I\sigma)t}$$

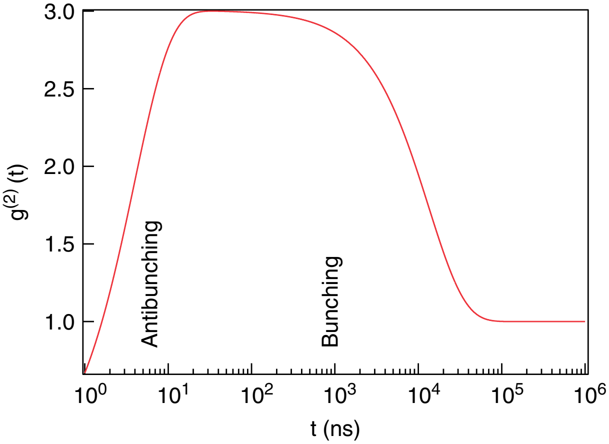

Fig. 17.2 Intensity autocorrelation function of the fluorescence of a single dye molecule under room-temperature excitation.

$$+\frac{k_{\text{isc}}^{\text{eff}}}{k_{\text{risc}}}e^{-(k_{\text{isc}}^{\text{eff}}+k_{\text{risc}})t} \tag{17.9}$$

where the effective intersystem crossing rate $k_{\text{isc}}^{\text{eff}}$ is given as

$$k_{\text{isc}}^{\text{eff}} = \langle n_2\rangle k_{\text{isc}} \tag{17.10}$$

The theoretical autocorrelation function of a single dye molecule according to Eq. 17.10 is shown in Figure 17.2 on a logarithmic timescale. This function drops to zero at the temporal origin, which is intuitively understood taking into consideration that a single quantum system can never emit two photons simultaneously. This behavior is referenced to as photon antibunching. Thereafter, the autocorrelation function takes a value above 1, indicating that the occupation probability of S_1 at this time is higher than on average. This is because the system will always be excited first to S_1, but on average the occupancy $\langle n_2\rangle$ is limited by the triplet bottleneck. Because of triplet excursions, a single molecule emits its photons in bunches (cycling in the singlet manifold under photon emission), separated by dark periods (when the molecule is shelved in the triplet state). Therefore, the second term in Eq. 17.10 is referred to as the *photon bunching*. If dynamical processes are to be studied by single-molecule fluorescence, care has to be taken that photophysical effects do not lead to misinterpretations.

17.2.2
Energy Transfer

Energy transfer between two or more fluorescent entities is a major subject in single-molecule fluorescence. It plays an important role in light harvesting complexes and, on the other hand, is the basis of one of the most popular single-molecule techniques, fluorescence resonance energy transfer (FRET), which is referred to as a *molecular ruler* (Stryer and Haugland, 1967) owing to its capability to measure distances between two fluorophores by spectral means.

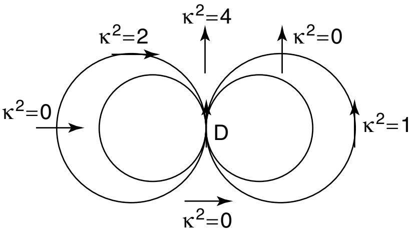

Fig. 17.3 Orientation factors κ^2 for different cases of relative donor–acceptor placement.

In FRET, one fluorophore, called *donor*, is excited, and the excitation energy is radiationless transferred to a nearby fluorpohore, called *acceptor*. The two chromophores may be chemically identical (homotransfer) or distinct (heterotransfer). The transfer mechanism is based on the dipole–dipole interaction between the two fluorophores in the weak coupling regime, that is, the interaction energy is small compared to the transition energies. The transfer efficiency theoretically derived by Förster (Förster, 1946) depends on the relative location and orientation of the transition dipoles of the fluorophores, their distance R, the refractive index of the medium n in the vicinity of both, and the overlap integral J. The latter takes account for the resonance condition and is the integral of the product of the normalized emission spectrum of the donor $F_D(\lambda)$ and the absorption spectrum (molar extinction coefficient in $\mathrm{cm}^{-1}M^{-1}$) $\varepsilon_A(\lambda)$ of the acceptor:

$$J = \int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 \, d\lambda \tag{17.11}$$

The transfer rate, that is, the rate with which the excited donor transfers its energy to the acceptor, is given as

$$k_t = 8.8 \times 10^{-23}\mathrm{mol}\frac{1}{\tau_\mathrm{D}}\frac{1}{\mathrm{R}^6}\frac{\kappa^2\Phi_\mathrm{D}}{\mathrm{n}^4}\mathrm{J}$$

$$= \frac{1}{\tau_D}\left(\frac{R_0}{R}\right)^6 \tag{17.12}$$

with the distance R taken in Ångstrom and R_0 the Förster radius. Here, the relative position and orientation of the dyes are taken into account via the orientation factor κ^2. Values of κ^2 for some cases are shown in Figure 17.3. The orientation dependence of the energy transfer rate may jeopardize distance measurements. Therefore, a free rotation of the fluorophores on a timescale faster than the fluorescence lifetime is aimed at, leading to an average orientation factor $\langle\kappa^2\rangle = 2/3$. Linkers with several carbon atoms are used to assure unhindered rotation of the dye. However, interactions between the dye and the protein may lead to blocking of the free rotation. Fluorescence anisotropy measurements provide information on the rotational flexibility of the dyes and should therefore always be conducted as a control. Fortunately, even a partial blocking of rotational freedom does not significantly alter the average orientation factor. If, for example, one of the dyes cannot rotate at all while the other one is free to rotate, the average orientation factor takes the value $\langle\kappa^2\rangle = 0.63$ (Berberan-Santos and Prieto, 1988).

In the experiment, the transfer rate is not directly accessible but rather the transfer efficiency, which is the fraction of transferred excitation quanta, and which is related to the distance R as

$$E_t = \frac{1}{1 + \left(\frac{R}{R_0}\right)^6} \tag{17.13}$$

Although in ensemble experiments the transfer efficiency is measured via comparison of donor fluorescence in the presence and absence of the acceptor (e.g., by photobleaching the acceptor), in single-molecule experiments the fluorescence signals of the donor F_A and the acceptor F_D are utilized:

$$E_t = \frac{F_A}{\gamma F_D + F_A} \tag{17.14}$$

The correction factor γ takes into account the quantum efficiencies of fluorescence of the donor and the acceptor and their respective detection efficiencies. If there is direct excitation of the donor (i.e., not FRET mediated), the acceptor signal needs to be corrected by subtraction of that signal. A very robust method to determine the transfer efficiency is based on the fluorescence lifetime of the donor τ_{D0} and τ_{DA} in the absence and presence of the acceptor:

$$E_t = 1 - \frac{\tau_{DA}}{\tau_{D0}} \tag{17.15}$$

The fluorescence lifetime of the donor without the acceptor is determined in a control sample.

In single-molecule FRET experiments, the photophysics of the dyes has to be treated carefully. Although triplet excursions of the donor simply render the whole donor–acceptor pair dark, the situation is more complex if the acceptor is in the triplet state. If only one excited singlet and triplet states are considered, one would expect that no energy transfer occurs and that all excitation quanta lead to an emission of the donor in this case, resulting in an anticorrelated fluctuation of the donor and acceptor fluorescence. The existence of higher excited states for the acceptor, however, in the singlet as well as in the triplet system, gives rise to other pathways for the excitation energy. In particular, FRET-type energy transfer can result in an excitation of the acceptor to a higher triplet state T_n. Depending on the efficiency of this transfer process, the donor fluorescence may increase, stay constant, decrease, or even completely vanish when the acceptor is triplet shelved (Maus *et al.*, 2001). The latter process is known as *singlet–triplet annihilation* (*STA*).

17.2.3
The Dye Molecule as a Dipole

Classically, a dye molecule can be treated as a dipole antenna. Therefore, its absorption and emission has the same anisotropy. Only the component of the electric field parallel to the absorption dipole axis can excite the fluorophore, and the probability of photon emission has the same shape as the emission intensity of a dipole antenna. This holds in an isotropic medium as well as in the vicinity of an interface between media with different refractive indices. If a fluorophore is, for example, located close to an interface to a medium with a higher refractive index (imagine a fluorophore in an aqueous surrounding close to a glass coverslip), most of its fluorescence is emitted toward the interface (Figure 17.4). Additionally, the

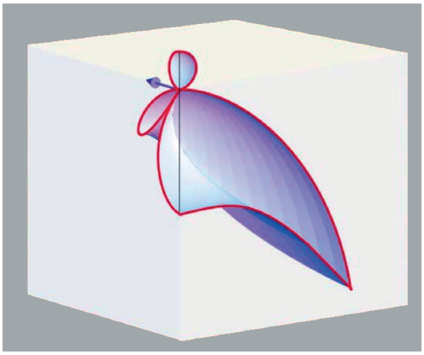

Fig. 17.4 Fluorescence emission characteristics of a dipole close to an interface to a medium with higher refractive index.

light emitted by a fluorophore is linearly polarized in the dipole direction. The anisotropy as well as the polarization of the emission can be exploited for the determination of the orientation of the dipole in space or even for the relative orientation of the dipoles in a donor–acceptor pair (Hübner *et al.*, 2004).

17.3
Techniques

17.3.1
Signal-to-Noise Considerations

The key prerequisite for successful single-molecule fluorescence experiments is a high signal-to-noise (SNR) ratio. The fluorescence signal in single molecule detection (SMD) is typically the photon count within a given time interval. Owing to the stochastic nature of photon emission, this photon number is Poisson distributed. The noise of the signal therefore is the shot-noise of the total number of detected photons. The total number of detected photons is composed of the signal itself and background contributions. The latter can be further divided into background, induced by the excitation laser, and the background signal coming from the detectors in the absence of any source of light, the dark signal.

The laser-induced background originates from elastic Rayleigh and inelastic Raman scattering, as well as from fluorescence in the optical system and the solvent where the molecule under observation is embedded. Its contribution is linearly dependent on the laser intensity. The dark signal, on the other hand, is a constant. The total SNR ratio can be given as

$$SNR = \frac{\eta_{\text{det}} \cdot R \cdot T_{\text{int}}}{\sqrt{\eta_{\text{det}} \cdot R \cdot T_{\text{int}} + C_b \cdot I_L \cdot T_{\text{int}} + N_d \cdot T_{\text{int}}}} = \frac{\eta_{\text{det}} \cdot R}{\sqrt{\eta_{\text{det}} \cdot R + C_b \cdot I_L + N_d}} \cdot \sqrt{T_{\text{int}}} \tag{17.16}$$

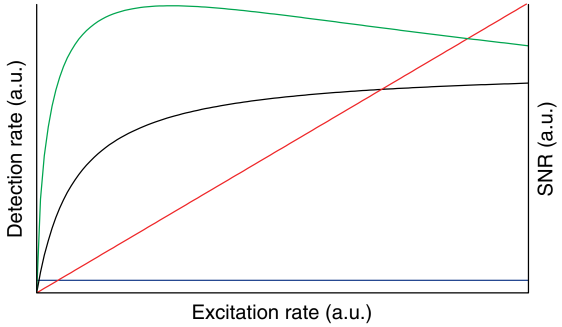

Fig. 17.5 Signal-to-noise ratio as a function of exitation laser intensity according to Eqs 17.16 and 17.6 (green). The fluorescence intensities of the single molecule (black), the dark signal (blue), and the laser-induced background (red) are also plotted.

where R is the emission rate of the fluorophore, T_{int} is the integration time, η_{det} is the detection efficiency, C_b is the constant of proportionality between laser intensity I_L and laser-induced background photon rate, and N_d is the dark count rate of the detector.

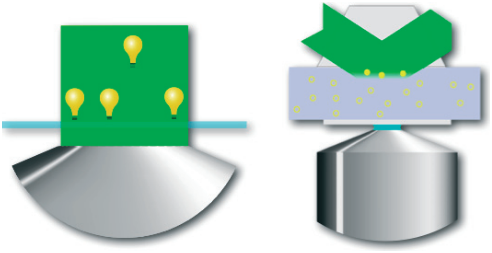
Saturation of the fluorescence signal leads to an optimum excitation rate for a given integration time where the SNR reaches its maximum, as shown in Figure 17.5.

17.3.2
Wide-Field Fluorescence Microscopy Techniques

In wide-field fluorescence microscopy, the whole field of view of an optical microscope is illuminated to excite fluorescence, and the whole field of view is also imaged onto a camera. The great advantage of wide-field microscopy is that, on the one hand, many molecules can be observed in parallel and that, on the other hand, the trace of a moving molecule can be followed. However, the time resolution is limited by the cameras in use.

For single-molecule fluorescence imaging, a very sensitive camera is necessary. If slow processes are to be followed, back-thinned cooled charge-coupled device (CCD) cameras are the best choice. Those CCDs convert incoming photons into electrons with an efficiency close to unity. However, the readout process of the charges introduces noise of typically a few electrons. Therefore, single-photon detection is not possible, and longer exposure times are necessary.

If single photons are to be detected with a camera and a short integration time is required, intensified cameras or electron multiplying CCDs (EMCCDs) can be used. Intensified CCDs have an image intensifier coupled to the CCD camera. The image intensifier is a multichannel plate photomultiplier (MCP-PM) with a phosphor behind the anode. Thus, an impinging photon is first converted into a photoelectron, which is multiplied in the PM, and the electron avalanche is back converted into light. The light from the phosphor is then detected by the CCD. Typical quantum efficiencies of the photocathodes of



(a) (b)

Fig. 17.6 Sketch of epifluorescence (a) and TIRF (b) illumination modes in wide-field microscopy.

image intensifiers are in the 10–20% range.

A great breakthrough in camera technology was the introduction of an electron multiplying or gain register in the CCD. In this register, the single charges are multiplied in an avalanche process principally similar to a PM. Thus, the single electron generated by a single photon is multiplied to a number that is higher than the readout noise and can therefore be detected. EMCCDs have the same high quantum efficiency of photon detection as CCDs close to unity.

The time resolution of a CCD camera is typically limited by the readout process. However, if only a short sequence of images is to be taken, the charges can be first shifted on the CCD chip and subsequently read out. Depending on the size of the image, exposure times in the submillisecond range are possible this way.

With respect to excitation of fluorescence, two different illumination modes can be applied, namely, conventional epifluorescence and total internal reflection (TIR) excitation as detailed later.

17.3.2.1 Epifluorescence Microscopy

The simplest way to observe the fluorescence of single fluorophores is by using a conventional epifluorescence microscope. Here, the whole field of view is illuminated by parallel laser light (Figure 17.6 (a)). Therefore, the laser is focused into the back focal plane of the microscope objective. This technique, however, requires a sample that is thinner than the focal depth of the microscope; otherwise, out-of-focus molecules would give rise to a high background signal. Such a thin sample is, for example, molecules tethered on the surface of a coverslip or embedded in a thin polymer film. A cell membrane also represents a thin sample, so that epifluorescence microscopy is the method of choice to study, for example, membrane diffusion (Schütz *et al.*, 2000).

17.3.2.2 TIRF Microscopy

If the requirement of a thin sample for epifluorescence microscopy is not fulfilled, illumination of out-of-focus molecules can be circumvented by TIR excitation. The excitation laser is totally reflected typically at a glass–water interface and only fluorophores in the evanescent field at the interface are excited. Depending on the angle of incidence and the wavelength of the laser, the evanescent field penetrates some 10 nm into the aqueous medium. The small penetration depth is advantageous with respect to lowering the background, but, on the other hand, prevents observation of features further away from the interface.

Two different realizations for TIRF excitation are used: objective-type TIRF and prism-type TIRF.

In objective-type TIRF, illumination is carried out similar to epifluorescence by focusing the laser in the back focal plane of an oil immersion microscope objective. In contrast to epifluorescence, this focus is offset from the optical axis so that the emerging parallel light is tilted by an angle larger than the critical angle for total reflection at the glass–water interface of 61°. The highest achievable tilt with an $\mathrm{NA} = 1.4$ oil immersion objective is 67°. Dedicated TIRF objectives have $\mathrm{NA} = 1.45$ corresponding to a maximum tilt angle of 73 °. The advantage of objective-type TIRF is that the fluorescence is collected trough the glass cover slip, in a direction where most of the fluorescence is emitted (cf. Figure 17.4). Thus, a high detection efficiency is assured.

In prism-type TIRF (Figure 17.6(b)), the laser is directed into a prism and the excitation occurs on the prism surface with TIR. In contrast to objective TIRF, the fluorescence is collected through the aqueous medium. Thus, the detection efficiency is considerably lower. The advantage of prism-type TIRF is the higher flexibility in the choice of the angle of incidence of the laser light.

17.3.3
Confocal Optical Microscopy

The main principle behind confocal optical microscopy invented by Marvin Minsky in 1957 (Minsky, 1957) is that a point light source and a point detector are both being imaged in the same position in the sample. The point spread function (PSF) of the microscope, that is, the image that is obtained from a point in the sample, therefore is the product of the two PSFs of illumination and detection. Typically, the microscope objective is used for both focussing the laser and detecting the fluorescence in an epi-illumination scheme, and excitation and fluorescence light are separated in a dichroic beam splitter as can be seen in Figure 17.7. The product of the excitation and detection PSFs defines the confocal volume of about 0.1 fl. The shape of the confocal volume depends on the illumination conditions, but can be approximated quite well by a three-dimensional Gaussian intensity distribution. The advantage of the smaller PSF is not primarily the slightly higher resolution but rather a considerable reduced background. Laser-induced background signal is in a first approximation proportional to the detection volume. Compared to wide-field microscopy, this volume is reduced by a factor of about $2^{3/2}$.

To obtain an image, the confocal volume is raster scanned across the sample. In contrast to wide-field microscopy, where all points of the image are obtained in parallel in a single exposure, in confocal microscopy the image is built in a serial manner, point by point. This results in a drastically prolonged time to record a single image as compared to wide-field microscopy.

To build the image, either the sample or the confocal volume is moved. For sample scanning, piezo-driven scan stages are used, whereas beam or laser scanning is realized by galvanometer mirror scanners. For the latter, a telecentric lens system generates an image of the

scanning mirrors in the back focal plane of the microscope objective. Thus, a tilt of the scanning mirror results in a shift to the confocal volume in the sample.

Sample scanning has the clear advantage that the light always propagates on the optical axis through the microscope objective. Therefore, aberrations due to tilt of the beam with respect to the optical axis such as coma or astigmatism are avoided. The allowed size of the image is only limited by the scan range. In contrast, in beam-scanning microscopes the size of the image is limited by the microscope objective. On the other hand, beam scanning also has several advantages: the achievable scan speed is considerably higher, the field of view can be changed by using microscope objectives with different magnifications, and the sample can be mounted in a cryostat.

The pointlike light source required for confocal imaging is realized either by the use of an excitation pinhole or by feeding the laser through a single-mode optical fiber. A fiber typically guarantees a perfect Gaussian mode, whereas a pinhole is advantegeous with respect to polarization control.

The other element defining the confocal volume is the detection pinhole. For single-molecule fluorescence experiments, the size of the confocal pinhole is chosen with respect to minimal loss of fluorescence signal. A diameter corresponding to the diameter of the airy disc turned out to be a good choice.

Key elements of the confocal microscope are the dichroic or multichroic beam splitter and the emission filters. Although in the past holographic notch filters were primarily used to block the back-scattered laser light, the development of even better dielectric filters has rendered them a cost-effective alternative. In particular, sputtered dielectric filters convince with steep edges, high optical density at the laser wavelength, high transmission in the pass band, and their ruggedness. Care should be taken that the filters are subpixel registered, that is, that they do not introduce beam deviations.

The confocal optical microscope is used in two different regimes for single-molecule experiments: in solution experiments, the confocal volume is placed stationary in the sample solution, and freely diffusing molecules lead to fluorescence bursts when they cross it. Thus, distributions of fluorescence properties of the molecules are obtained. If there is dynamics present on a timescale faster than the transit time, this dynamics can be studied. Dynamics on longer timescales, however, is not accessible with this method.

In immobilized experiments, the Brownian motion is prohibited by appro priate immobilization techniques such as embedding in a gel or tethering to a surface. The confocal volume is placed on a particular molecule localized earlier by an image scan, and the (transient) fluorescence is recorded. In this manner, dynamical processes on all timescales can be studied.

17.4
Applications

17.4.1
Protein Folding

The mechanism by which the unstructured polypeptide chain of a protein finds its unique structure remains one of the great mysteries in protein biophysics. It is believed that there is not one single pathway but rather a bunch of ways from the ensemble of unstructured chains to the final three-dimensional structure. This heterogeneity is an appealing target for single-molecule studies. Its ability to resolve subensembles allows for the study of the unfolded state and of folding kinetics and chain dynamics under equilibrium conditions, where either of the folded or unfolded state is weakly populated.

17.4.1.1 The Unfolded State

The best-studied subject in protein folding with single molecules is the unfolded state. The interest for the unfolded state arises from the idea that knowledge about its conformation and dynamics under nativelike conditions provides information about the initial steps on the folding pathway. In the first experimental single-molecule FRET study, the well-investigated protein chymotrypsin inhibitor 2 was specifically labeled with tetramethylrhodamine as the donor and Cy5 as the acceptor (Figure 17.8(a)) (Deniz *et al.*, 2000). The confocal volume was placed in the sample solution, and brownian diffusion gave rise to a burst of fluorescence each time a molecule was passing by. Each burst was analyzed with respect to the transfer efficiency and added to a histogram. In this manner, a distribution of FRET efficiencies is obtained. The histograms shown in Figure 17.8(b) consist of two distinct, rather broad peaks, corresponding to the folded state (high transfer efficiency) and the unfolded state (low transfer efficiency). From the areas under the peaks, the concentrations of the folded and unfolded state can be directly obtained. Strikingly, the center position of the unfolded peak shifts to higher transfer efficiencies with decreasing denaturant concentration, as can be seen in Figure 17.8(c). This shift is indicative of a compaction of the unfolded polypeptide chain under nativelike conditions.

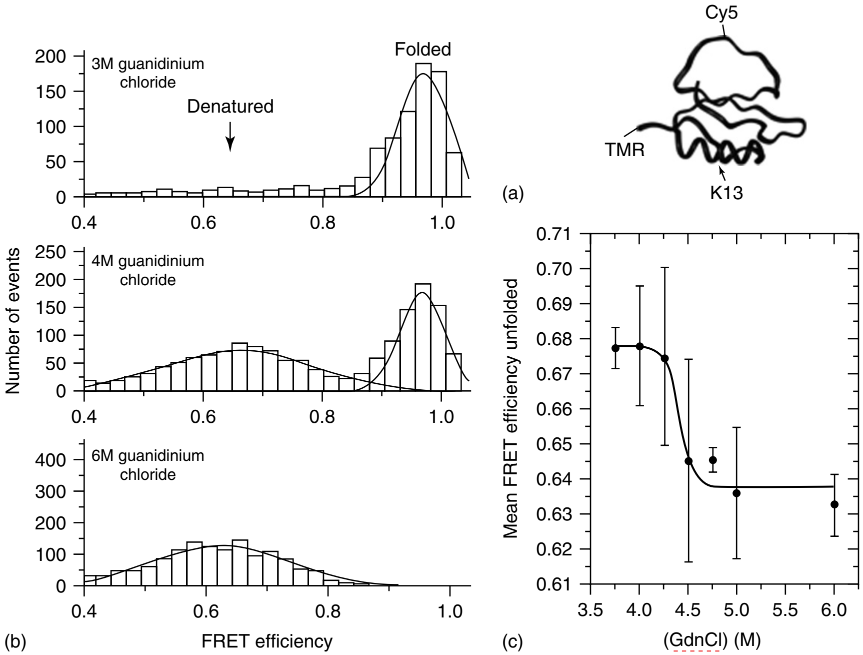

Fig. 17.8 (a) A structural sketch of chymotrypsin inhibitor 2 showing the labeling sites with tetramethylrhodamine as the donor and Cy5 as the acceptor. (b) Energy transfer histograms for different GdnCl concentrations. (c) Mean FRET efficiency as a function of denaturant concentration. (Adapted from Deniz *et al.* (2000).)

Using the same methodology, Schuler *et al.* studied the folding transition of the cold shock protein from *Thermotoga maritima* (Schuler, Lipman and Eaton, 2002). Csp*Tm* was labeled with a donor and an acceptor dye (Figure 17.9(a) and (b)), and single-molecule bursts were analyzed for their FRET efficiency and compiled in a histogram shown in Figure 17.9(c). Again, a compaction of the unfolded chain is observed (Figure 17.9(d)). Furthermore, from the finding that the width of the transfer efficiency distribution is shot-noise limited, it can be concluded that the reconfiguration time is considerably shorter than the transit time of the molecule through the focus. Thus, an upper limit for the reconfiguration time for the polypeptide chain is obtained, which allows for estimating a lower bound for the energy barrier height between the unfolded and folded state of the protein.

Recently, Hofmann *et al.* have studied the influence of different denaturants, namely, guanidinium chloride (GdnCl) and urea, on the collapse of the unfolded chain of the model protein barstar (Hofmann *et al.*, 2008). Using the same FRET pair as Schuler *et al.*, the subpopulation-resolved transfer efficiencies were measured as a function of denaturant concentration. It was found that for low denaturant concentrations, in the salt GdnCl the chain is more compact than in urea. One possible explanation for this finding is that the charges in the polypeptide chain are shielded in GdnCl, thus reducing electrostatic repulsion. This

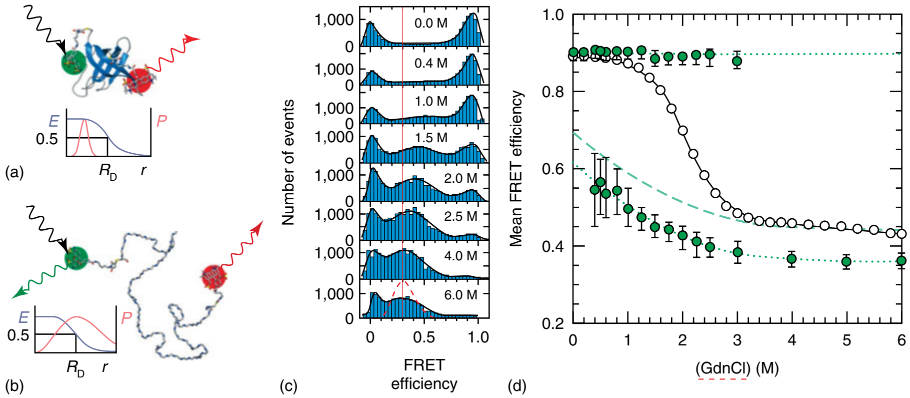

Fig. 17.9 The doubly labeled protein CsP*Tm* in the folded (a) and unfolded (b) state additionally showing the label-distance distribution and the distance-dependent FRET efficiency. The donor dye AlexaFluor 488 is shown in green and the acceptor AlexaFluor 594 in red. (c) The distributions of apparent FRET efficiencies of single CsP*Tm* molecules diffusing through the confocal volume for increasing GdnCl concentrations. The three peaks can be associated to (from left to right) molecules missing: an acceptor dye, unfolded, and folded molecules, respectively. (d) Mean transfer efficiencies derived from the histograms for the folded and unfolded population (the open circles). (Adapted from Schuler, Lipman and Eaton (2002).)

interpretation was further evidenced by unfolding data in urea and the addition of salt, showing a clear compaction of the chain upon addition of salt. This experiment shows that electrostatic interactions are important determinants of the conformation of the unfolded peptide chain.

The dynamics of the unfolded chain of donor–acceptor-labeled Csp*Tm* was directly monitored by Nettels *et al.*, with a sophisticated technique based on a Hanbury-Brown and Twiss detection scheme (Nettels *et al.*, 2007). With this method, the intensity autocorrelation function can be measured down to the nanosecond timescale by circumventing the dead time of the detectors using a pair of them. Chain dynamics associated with fluctuations of the donor–acceptor distance correspondingly results in intensity fluctuations of the donor and acceptor. Thus, the intensity autocorrelation shows a decay on the timescale of the fluctuations. Figure 17.10 shows the donor and acceptor interphoton-time histograms for the unfolded population featuring photon antibunching on the nanosecond timescale typical for a single emitting quantum system. Strikingly, an additional decay of the correlation function is found. The time constant of this exponential decay is 44 nanoseconds, being the reconfiguration time of the chain, which is related to the attempt frequency to cross the energy barrier separating the unfolded and folded state. Thus, single-molecule photon statistics is a valuable tool for the study of chain dynamics associated with the folding reaction.

17.4.1.2 Single Molecule Folding/Unfolding Transitions

A direct observation of folding/unfolding transitions succeeded for the protein adenylate kinase from *Escherichia coli*, immobilized by encapsulation in

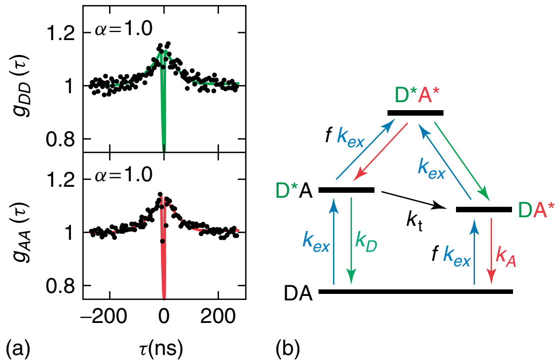

Fig. 17.10 (a) Interphoton-time histogram of donor (top) and acceptor (bottom) fluorescence showing antibunching at short times and a correlation on the 100-nanoseconds timescale. (b) Photophysical model with the ground states A and D and the respective excited states A* and B*. Fluctuations of k_t lead to the decay in the correlation functions shown in (a). (Adapted from Nettels *et al.*, (2007).)

surface-tethered vesicles (Rhoades, Gussakovsky and Haran, 2003). The protein is labeled with a donor–acceptor pair, and their fluorescence is transiently recorded as a function of time. Therefore, the confocal volume is centered on a vesicle with an encapsulated protein. Surprisingly, rather slow transitions between the two states are occasionally observed (Figure 17.11(a)). These slow transitions might indicate the search for the folding pathway in the rugged energy landscape between the folded and unfolded state. Further evidence for the existence of local minima in this landscape is provided by the finding of small steps in the transfer efficiency indicating partial folding/unfolding events (Figure 17.11(b)). Furthermore, there is a broad distribution of step sizes for both, folding and unfolding transitions (Figure 17.11(c)). The stochastic nature of the walk on the energy landscape renders it impossible to observe those in ensemble experiments, clearly pinpointing the advantage of the single-molecule approach.

17.4.2
Enzymes

Single-molecule investigations of enzymatic activity are very appealing for a number of reasons. The most obvious one is common to all single-molecule experiments: the study of heterogeneity. Single-molecule fluorescence, on the other hand, also allows measurements of enzyme kinetics under equilibrium conditions. Furthermore, under nonequilibrium conditions, the system may remain stationary, that is, the concentration of educts and products stays almost constant, due to the low enzyme concentration in single-molecule studies. Eventually, the investigation of conformational changes associated with enzymatic activity may elucidate the mechanisms of catalysis.

17.4.2.1 Static and Dynamic Heterogeneity

The prototype experiment for the study of static and dynamic heterogeneity in enzyme activity was performed by Xie and

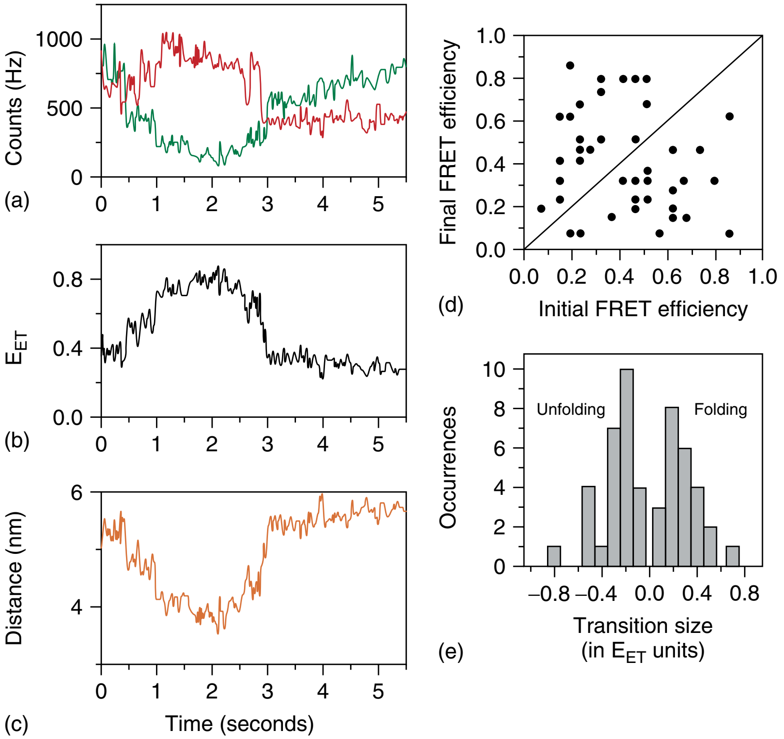

Fig. 17.11 (a) Transient donor and acceptor intensities for a single adenylate kinase molecule inside a vesicle. The anticorrelated behavior is indicative of a change in FRET efficiency shown in (b), which can, in turn, be related to a donor–acceptor distance change shown in (c). (d) Distribution of initial/final FRET efficiencies for folding (below the diagonal line) and unfolding (above the diagonal line) transitions. (e) Distribution of FRET efficiency step sizes of folding/unfolding. (Adapted from Rhoades, Gussakovsky and Haran (2003).)

coworkers with the enzyme cholesterol oxidase (COx) (Lu, Xun and Xie, 1998). FAD, the cofactor of this enzyme, is fluorescent in the oxidized and nonfluorescent in the reduced state. During enzymatic turnover, FAD switches between the oxidized and reduced states.

The COx molecules are embedded in an agarose gel (Figure 17.12(a)), thus freezing their translational mobility while preserving rotational freedom. The latter is very important to avoid fluctuations in the fluorescence signal due to slow reorientation. The confocal volume was centered at one COx molecule, and FAD fluorescence recorded as a function of time.

Binary jumps in the transient fluorescence intensity as shown in Figure 17.12(b) are indicative of cycling between the fluorescent and nonfluorescent state of FAD. Thus, the catalytic activity is directly accessible, where one turnover is just one cycle of high and low fluorescence intensity. The steady-state kinetics can be obtained from the distributions of the on and off states of the fluorescence corresponding to the two modifications of FAD within the reaction cycle. Thereby, both half-cycles of

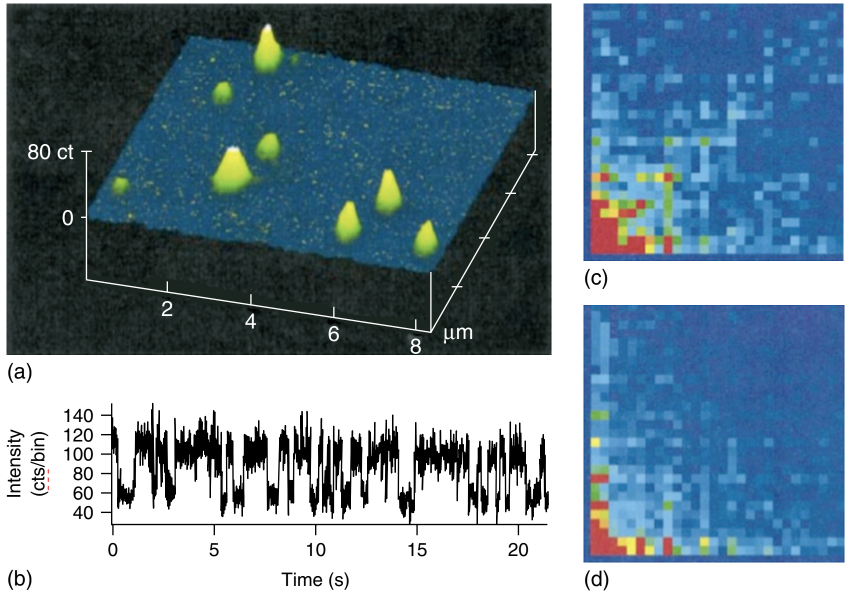

Fig. 17.12 (a) Fluorescence intensity image showing single-Cox molecules. (b) Transient fluorescence intensity of a single-Cox molecule showing binary on/off behavior. (c) and (d) Two-dimensional conditional probability distribution for a pair of two adjacent on-times (a) and for a pair of on-times separated by 10 turnovers. (Adapted from Lu, Xun and Xie (1998).)

the reaction can be analyzed within one single-molecule experiment.

Strikingly, there is a rather broad distribution of the on-times corresponding to the FAD reduction half-cycle for 33 COx molecules, indicative of static disorder, that is, different enzymatic activities of the different enzyme molecules. Now the question arises if there is also dynamic disorder, which is a fluctuation in enzymatic activity over time. To address this question, pairs of on-times separated by a defined number of turnovers are considered and their conditional probabilities calculated. If an on-time of a certain duration is with a high probability followed by an on-time of the same length after this certain number of turnovers, the conditional probability is high. If there is no correlation between the length of the pairs of on-times seperated by the number of turnovers, the conditional probability is low. In a two-dimensional conditional probability distribution histogram, a diagonal feature is evidence for a correlation of the on-time durations of on-states. Such a feature is visible for adjacent on-times (Figure 17.12(c)), but absent for on-times separated by 10 turnover cycles (Figure 17.12(d)). A covariance analysis even allows for the determination of the characteristic timescale for the fluctuations in catalytic activity. Fluctuations of the spectral mean of FAD emission in the absence of cholesterol on the same timescale are interpreted in terms of conformational changes, with the simplest model of interchange between two conformational substates.

Edman and Rigler have used a similar approach for the study of catalytic activity of the enzyme horseradish peroxidase (Edman and Rigler, 2000). Using dihydrorhodamine 6G as a substrate that is nonfluorescent, the catalytic turnover can be followed by the generation of the product rhodamine 6G. The memory landscapes of different proteins are indicative of non-Markovian behavior. Furthermore, oscillations in these memory landscapes can be interpreted by a model where the molecule passes through a number of inactive (conformational) substates and one active substate.

Recently, static heterogeneity was also reported for single-enzyme molecules using a fluorescence-based activity assay with much larger statistics (Rissin, Gorris and Walt, 2008). However, this experiment was based on the determination of product concentration and is therefore not capable of accessing the turnovers of a single-enzyme molecule.

17.4.2.2 **Conformational Changes and Catalytic Activity**

The prime example for the study of conformational dynamics of single-enzyme molecules is the rotation of F_0F_1 ATPase (Kagawa and Racker, 1966). This membrane protein synthesizes ATP from ADP and phosphate driven by a proton gradient across the membrane. The stepwise rotary motion was first directly observed by videomicroscopy of a fluorescent actin filament attached to the F_1 part (Noji *et al.*, 1997). Although ensemble methods are able to show that rotation occurs, only single-molecule experiments allow for resolution of a sequence of steps. After this key experiment, the rotation was investigated by different single-molecule fluorescence methods Rondelez *et al.* (2005); Yasuda *et al.* (2003); Yasuda *et al.* (2001); Hisabori, Kondoh and Yoshida (1999); Iino *et al.* (2005); Itoh *et al.* (2004); Masaike *et al.* (2000); Nishizaka *et al.* (2004); Adachi *et al.* (2007); Kaim *et al.* (2002); Börsch *et al.* (2002); Diez *et al.* (2004); Zimmermann *et al.* (2006); Steigmiller *et al.* (2004). Kaim *et al.* show by polarized detection the stepwise rotation of complete F_0F_1 ATPase from *Propionigenium modestum* both in synthesis and hydrolysis (Kaim *et al.*, 2002). Therefore, the c subunit was labeled by a fluorescent dye with two linkers in order to assure rigid joining (Figure 17.13(a)). From the transient fluorescence detected in two channels corresponding to orthogonal polarizations the polarization P can be calculated according to

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \tag{17.17}$$

The time-dependent polarization in the presence of ATP and Na^+ in Figure 17.13(b) shows stepwise changes between three levels, indicating rotational motion in three steps. A data analysis by means of the autocorrelation function of the transient polarization revealed that a model with three pairs of $90\,^\circ/30\,^\circ$steps as proposed by Yasuda *et al.* (Yasuda *et al.*, 2001) was most consistent with the data.

Single-molecule FRET experiments were also able to show stepwise rotation of F_0F_1 ATPase. Incorporating doubly labeled ATPase (Figure 17.13) in liposomes freely diffusing in solution, Diez *et al.* recorded FRET efficiency transients during passage of the liposomes through the focal volume (Diez *et al.*, 2004). Those transients show stepwise changes both in hydrolysis and in synthesis between three levels (Figure 17.13(d)

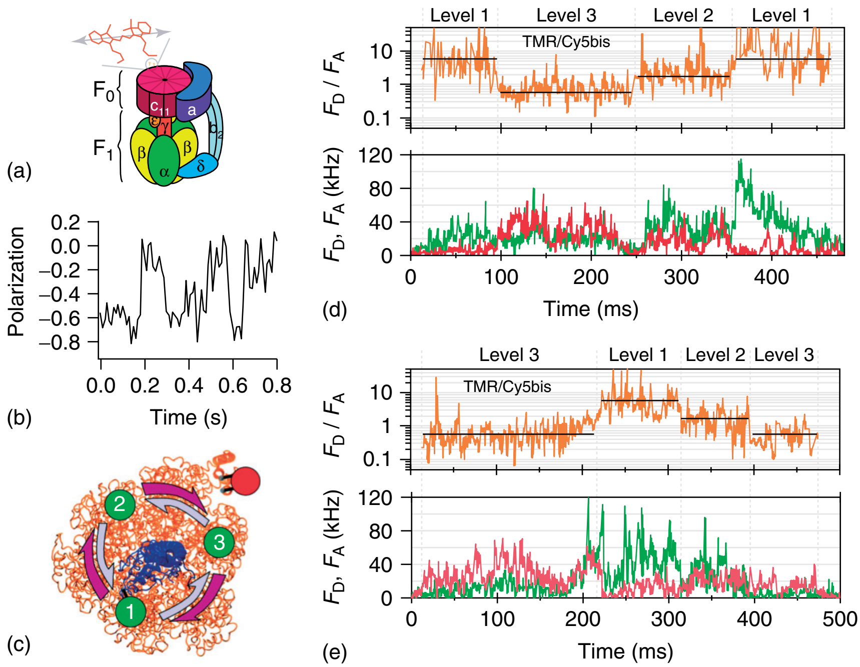

Fig. 17.13 F_0F_1 ATPase labeled at the c subunit (a) shows steps in the polarization transient (b). Donor–acceptor-labeled ATPase (c) exhibits jumps between three levels in the ratio between the fluorescence of the donor and acceptor both in hydrolysis (d) as well as in synthesis (e) with reversed order. (Adapted from Kaim *et al.* (2002) and Diez *et al.* (2004).)

and (e)). Strikingly, the order of the levels is reversed in hydrolysis/synthesis, thus elegantly demonstrating the reverse of rotation. Recently, Yasuda *et al.* were able to identify the transiently populated ATP waiting conformation by single-molecule FRET experiments on immobilized ATPase molecules (Yasuda *et al.*, 2003).

The first single-molecule FRET demonstration of conformational dynamics associated with enzymatic activity succeeded with the enzyme *staphylococcal nuclease* (SNase) in the group of Shimon Weiss (Ha *et al.*, 1999). SNase labeled with a donor–acceptor pair showed fluctuations of the transfer efficiency that can be quantitatively analyzed in terms of the autocorrelation function of the transfer efficiency shown in Figure 17.14. The decay in the E_t autocorrelation function can be fit by an exponential with time constants ranging from some tens to thousands of milliseconds, with an average of 41 milliseconds. In the presence of pTp, a known inhibitor of SNase activity, this mean is shifted to 133 milliseconds. Therefore, it can be concluded that the inhibitor affects the conformational flexibility that is essential for SNase function. By labeling of the SNase with donor and the DNA substrate with the acceptor, SNase activity can be directly monitored via the association time, which is the time period of high FRET efficiency. A clear difference in association times is observed if the DNA is labeled either at the 5′ or 3′ end. This difference is

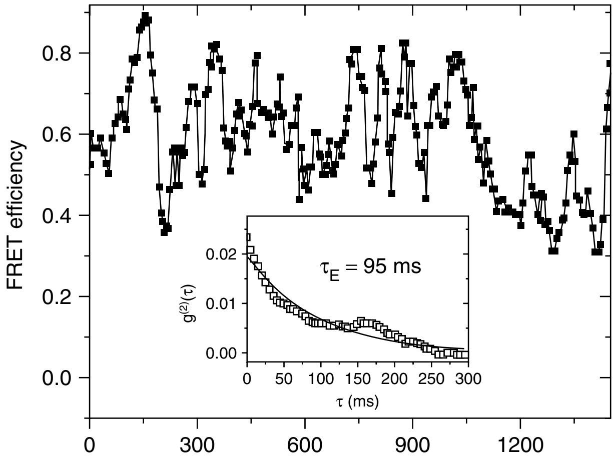

Fig. 17.14 FRET efficiency fluctuations of a single SNase molecule immobilized on a coverslip. The inset shows the autocorrelation function of the the FRET efficiency together with an exponential fit. (Adapted from Ha *et al.* (1999).)

in agreement with SNase processivity in the 3′–5′ direction.

Quenching of the dye AlexaFluor 488 was exploited for the investigation of conformational transitions of the enzyme dihydrofolate reductase (DHFR) (Zhang *et al.*, 2004). DHFR is a two-substrate enzyme catalyzing the reduction in dihydrofolate (DHF) to tetrahydrofolate (THF) by NADPH. To this end, AlexaFluor 488 was specifically attached to the structural loop that closes over the substrates after binding. Single- DHFR molecules were tethered on biotynilated cover slips via a biotin–streptavidin–biotin sandwich. In a TIRF illumination wide-field set-up, the transient intensities of many DHFR molecules could be recorded in parallel by an intensified CCD camera. Upon addition of DHF, conformational dynamics manifests itself in intensity fluctuations of the Alexa dye. In the simplest model, DHFR is switching between two conformational states with an opening and closing rate. Thus, using a threshold criterion, open and closed states can be assigned, delivering the dwell times in the respective states. The histograms of the dwell times provide the rates of opening and closing. From the concentration dependence of the closing rate in conjunction with transient ensemble kinetics measurements a model can be derived where rapid binding of DHF is followed by a conformational change.

Henzler-Wildman *et al.* have investigated the conformational heterogeneity and dynamics of Adk from *aquifex aeolicus* by X-ray crystallography, molecular dynamics simulations, NMR spectroscopy, and smFRET (Henzler-Wildman *et al.*, 2007). Adk is a two-substrate enzyme catalyzing phosphotransfer between AMP and ATP in the presence of Mg^{2+}. From X-ray crystallography in the presence of the substrates it is known that a conformational change occurs when the substrates are bound. Adk was specifically labeled with AlexaFluor 488 as the donor and AlexaFluor

633 as the acceptor at the two substrate-binding lids. First, freely diffusing Adk was investigated, and burstwise histograms of the transfer efficiencies were derived. Surprisingly, even in the absence of any substrate, Adk shows at least two subpopulations, where one corresponds to the conformation where both lids are opened and the other one corresponds to the closed conformation, which can be concluded by comparing the distances from the FRET experiments with crystallographic data. Upon addition of the inhibitor diadenosin pentaphosphate (AP5A), the equilibrium between the two conformations shifts toward the closed conformation.

To study the dynamics of conformational exchange, labeled Adk was immobilized on a functionalized cover slip via a His_6 tag. In spite of the considerable noise level, which results from the short integration time dictated by the required time resolution, transitions between the open and closed states can be observed. The overlap of the transfer efficiency histograms of two conformations renders a single threshold criterion for the discrimination of the two states unusable. Instead, a threshold zone was defined, where a change-of-state required a complete crossing of the zone. After assignment of the open and closed states, respectively, the dwell times in these states are compiled in histograms. From the histograms shown in Figure 17.15(a) and (b) the rate constants for opening and closing are derived. The values found for both cases, $k_{\text{open}} = 6500 \pm 500\,\text{s}^{-1}$ and $k_{\text{close}} = 2000 \pm 200\,\text{s}^{-1}$ for the substrate-free and $k_{\text{open}} = 40 \pm 20\,\text{s}^{-1}$ and $k_{\text{close}} = 350 \pm 200\,\text{s}^{-1}$ for the inhibitor-loaded enzyme, turn out to be very similar to the rates of chemical exchange found by NMR.

The assignment of open/closed states based solely on the apparent FRET efficiency is error-prone due to photophysical processes, which may also lead to fluctuations in the apparent FRET efficiency. It needs to be checked explicitly whether anticorrelated intensity changes of the donor and acceptor fluorescence signals occur. Therefore, a correlation analysis was performed. Clear evidence for anticorrelated behavior of donor–acceptor fluorescence intensity is provided by an anticorrelation in the donor–acceptor cross-correlation function as can be seen in Figure 17.15(c). At shorter times, a correlated fluctuation of donor and acceptor fluorescence is found, which is attributed to triplet dynamics of the donor and/or triplet dynamics of the acceptor and efficient STA. A global fit of the three correlation functions, namely, the donor and acceptor autocorrelation and their respective cross-correlation functions, provides the overall rate of distance dynamics and triplet kinetics. The overall rate of distance dynamics of $k_{\text{tot}} = 7000 \pm 2000\,\text{s}^{-1}$ is in good agreement with the rate from NMR and from the states analysis. During catalysis, opening and closing rates of $k_{\text{open}} = 40 \pm 10\,\text{s}^{-1}$ and $k_{\text{close}} = 1000 \pm 500\,\text{s}^{-1}$ are found matching the NMR data on chemical exchange. Taking into account that NMR can only provide information about the occurrence and timescale of dynamics, but no spatial information, these experiments nicely demonstrate that single-molecule FRET experiments perfectly complement other biophysical methods.

Single-molecule FRET experiments have also been performed on *E. coli* AdK, where opening and closing rates of $k_{\text{open}} = 120 \pm 40\,\text{s}^{-1}$ and $k_{\text{close}} = 220 \pm$

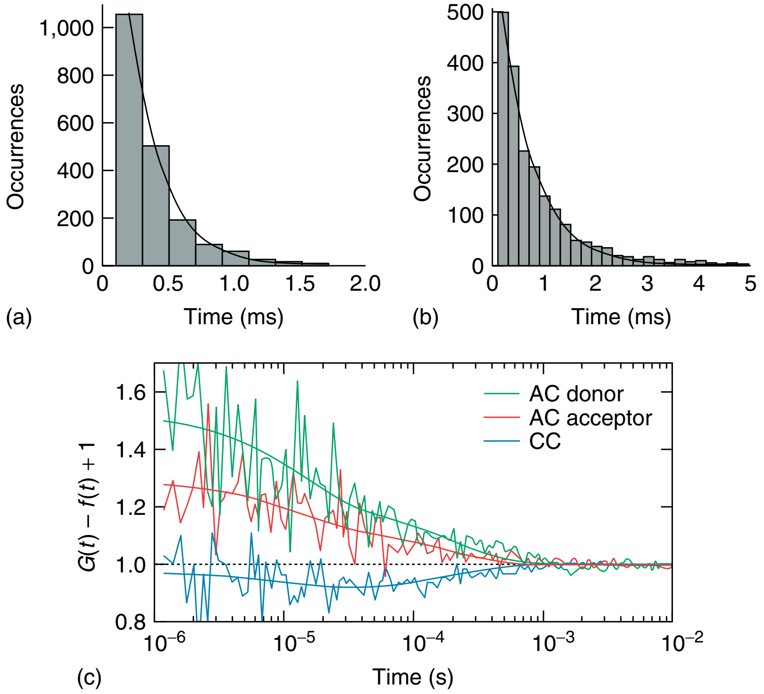

Fig. 17.15 Histograms of (a) low FRET efficiency and (b) high FRET efficiency states in the transient fluorescence of doubly labeled adenylate kinase from aquifex aeolicus attributed to an open and closed conformation. 70 s^{-1} were found for substrate-free Adk (Hanson *et al.*, 2007).

17.5 Conclusions

In recent years, single-molecule fluorescence has proven to be a valuable tool to obtain information on the conformational dynamics and heterogeneity of proteins that is not accessible by ensemble methods. However, the method is still far from being routinely applicable, mostly for problems with photophysics and photochemistry of the dye molecules. There have been several attempts made to improve the photostability of the dyes, but what works out for a particular dye may be even counterproductive for another. More effort has to be made on both synthesizing new dyes with better stability (Weil *et al.*, 2005) and improving the photostability of existing dyes (Rasnik, McKinney and Ha, 2006).

On the other hand, the noisy signal of a single molecule remains a challenge for data analysis, which might be confronted by methods such as Hidden–Markov modeling (McKinney, Joo and Ha, 2006).

21.1
Introduction

Ultrafast laser spectroscopy has evolved over the past 30 years from a somewhat esoteric area on the borders of chemistry and physics to become one of the major tools in molecular, materials, and life sciences. Much of this evolution has been driven by advances in technology, particularly, the development of the Kerr lens mode-locked titanium sapphire laser and subsequent progress in the design of optical parametric amplifiers (OPA). In this chapter, we briefly focus on these developments and outline the common methods of laser pulse characterization. We then describe some of the most widespread methods of modern ultrafast spectroscopy and indicate some of their capabilities.

21.2
Ultrafast Lasers

Short pulses are generated from a laser by modulating the gain at the round trip frequency of the laser. There are many methods of achieving such a modulation, including intracavity acousto-optic modulators and saturable absorbers (Svelto, 1998). The result is a series of pulses at a repetition frequency, which is the inverse of the round trip time and a temporal width, which is ultimately limited by the gain bandwidth of the lasing medium. The earliest studies of molecular dynamics were made with flash lamp pumped mode-locked Nd : YAG and Nd glass lasers (Kaufmann *et al.*, 1975). These sources were, by modern standards, unstable, difficult to use, and dangerous, but nevertheless readily produced picosecond pulses of very high intensities at low repetition rates. However, the first truly ultrafast experiments were made with mode-locked dye lasers. Subpicosecond pulses could be generated from dye lasers because the gain bandwidth of the laser medium is much larger than that for Nd lasers. Although very short pulses were obtained (<50 fs), the technical difficulties associated with these devices were considerable and their stability poor, making ultrafast spectroscopic measurements challenging (Kaufmann *et al.*, 1975; Fork *et al.*, 1981).

Important progress in ultrafast pulse generation was made with the discovery of solid state materials with very broad gain spectra, most notably titanium sapphire, which has a bandwidth capable of supporting pulse widths

ISBN: 978-3-527-40773-6

<10 fs. Titanium sapphire lasers were first mode-locked by traditional intracavity gain modulation methods, but the remarkable discovery that, once initiated, the mode-locking would continue without active modulation was the trigger for the development of a new generation of all solid state ultrafast lasers (Spence *et al.*, 1991). It was quickly discovered that the mechanism for self mode-locking was a nonlinear interaction in the gain medium, which becomes more effective with shorter pulses. With careful correction for group velocity dispersion by intracavity prisms, pulses as short as 15 fs can be extracted directly from the Ti : sapphire laser.

Ti : sapphire also has suitable energy storage properties, which allow it to act as a gain medium for pulse amplification. Amplifying such short pulses to high energies creates enormous peak powers (peak power = energy per pulse per pulse width), which would ultimately destroy the amplifier cavity. To overcome this problem, the method of chirped pulse amplification was developed (Perry and Mourou, 1994). The broad spectrum of the input pulse is spread in time using gratings and prisms such that the pulse width reaches several hundred picoseconds. The broad pulse can then be safely amplified and recompressed to yield pulses of up to millijoule scale energy and tens of femtosecond's width. With careful focusing, terawatt powers are achievable.

Short high peak power amplified pulses from solid state sources also have excellent beam profiles. Such pulses are suitable for pumping OPAs, which, when seeded with broad bandwidth pulses generated through self-phase modulation, can convert approximately 800 nm output of the Ti : sapphire laser into ultrafast pulses at any wavelength between the visible and near IR (Cerullo and De Silvestri, 2003; Wilhelm *et al.*, 1997). Such pulses may thus be used to study the electronic spectroscopy of almost any molecule. The OPA outputs two frequencies, called the *signal* and the *idler*, which may themselves be mixed in another nonlinear crystal to generate the difference frequency in the mid IR region (Towrie *et al.*, 2003). In this way, ultrafast spectroscopy can be performed in the vibrational energy region. The availability of short stable pulses at any frequency has stimulated a range of novel and imaginative range of ultrafast experiments, some of which are mentioned below.

21.3
Ultrashort Pulse Width Measurements

Pulses with tens of optical cycles in the near infrared spectral region are now commonly encountered in research laboratories worldwide. These pulses, which are on the femtosecond time scale, are much faster than any electronic measuring equipment can possibly capture. New methods to time resolve events on the ultrashort time scale have to be developed. In reality, the knowledge related to the generation of ultrashort pulses and the methods for their characterization evolved simultaneously, because it is essential to know the distortions and constraints that limit the production of even shorter pulses. In addition, for experiments utilizing ultrashort pulses, it is necessary at least to know the time duration of such pulses to determine the time resolution of the experiment.

Presently, there are very sophisticated methods that cover a wide range of time scales and produce a complete characterization of ultrashort pulses, that is, not only information about temporal duration but also about phase and amplitude in time and frequency domains. These methods, of which frequency resolved optical gating (FROG) (Trebino *et al.*, 1997) is the best known, are not treated here. Rather we describe the most fundamental technique, which estimates the time duration of ultrashort pulses with good precision. This technique relies on the condition that the ultrashort pulse itself is used to determine its time duration; an autocorrelation process (Jean-Claude and Rudolph, 1996). The setup most widely used is based on the well-known Michelson interferometer. However, linear processes such as a simple interferogram can only produce information about the coherence of the pulse, which is related to the spectral content. To access information about the time duration, it is necessary to work with nonlinear processes, such as second harmonic generation (SHG) in a nonlinear crystal, two-photon absorption, optical Kerr gate, and so on (Boyd, 2003), which enable the measurement of the intensity autocorrelation (Rulliere, 1998).

21.3.1
Autocorrelation Measurements

A typical setup for an intensity autocorrelator is shown in Figure 21.1. A beam splitter divides an incoming pulse into two equal intensity pulses which are then focused to a common spot where a crystal with, for example, a second-order nonlinearity is positioned. The path length difference and consequently the relative delay time (τ) between the two pulses can be adjusted mechanically via a variable delay stage. If the arm length difference is made small, so that the pulses overlap temporally inside the nonlinear crystal, the process of second harmonic (or more generally sum frequency) generation occurs in the phase matched direction separated spatially from the incoming beams and their second harmonics. The intensity of the newly generated beam can be measured

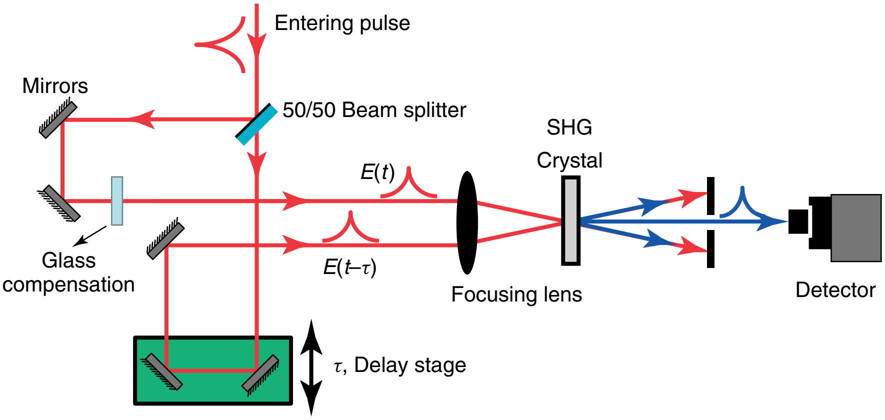

Fig. 21.1 Scheme for an intensity autocorrelator. SHG, second harmonic generation. Solid black lines are the laser fundamental, the dashed line is the second harmonic generated when the pulses overlap.

with a time integrating detector at each delay step introduced by the delay stage. If the relative time delay is increased, so that the overlap of the two pulses in the crystal is reduced, the second harmonic signal becomes weaker and ultimately disappears. The overall result is the intensity of the second harmonic signal as a function of delay time, which carries information about the incoming pulse duration.

21.3.2
Autocorrelation

The mathematical description of an autocorrelation process can be written as follows:

$$G^{(n)}(\tau) = \int_{-\infty}^{\infty} f^{n}(t) f^{n^*}(t-\tau)dt \quad (21.1)$$

where $f(t)$ is some time-dependent function and $f^*(t)$ is its complex conjugate (Jean-Claude and Rudolph, 1996). The function $G^{(n)}(\tau)$ is called the nth-order autocorrelation. Taking $f(t)$ as the resulting electric field from the two pulses inside the crystal, $f(t) = E(t) + E(t-\tau)$, and assuming a second-order process, it is possible to write the resulting signal as

$$G^{(2)}(\tau) = \int_{-\infty}^{\infty} \left|(E(t) + E(t-\tau))^2\right|^2 dt \quad (21.2)$$

where $G^{(2)}(\tau)$ is the second-order autocorrelation as a function of the delay time, τ. This equation can be separated into three terms: one centered at zero frequency, which is known as the *intensity autocorrelation plus a constant background*; the other two terms are centered at the optical frequency, ω, and second harmonic, 2ω, and are known as the *interferometric autocorrelation* (Jean-Claude and Rudolph, 1996). An example of an interferometric second-order autocorrelation measurement is presented in Figure 21.2(b). Most often the intensity autocorrelation, which is easier to measure than an interferometric autocorrelation, produces sufficient information to determine the time resolution of a given experiment. The intensity autocorrelation expression can be written as

$$I^{(2)}(\tau) = \int_{-\infty}^{\infty} I(t)I(t-\tau)dt \quad (21.3)$$

where $I(t) \propto |E(t)|^2$ is the time-dependent intensity of the pulse. An example

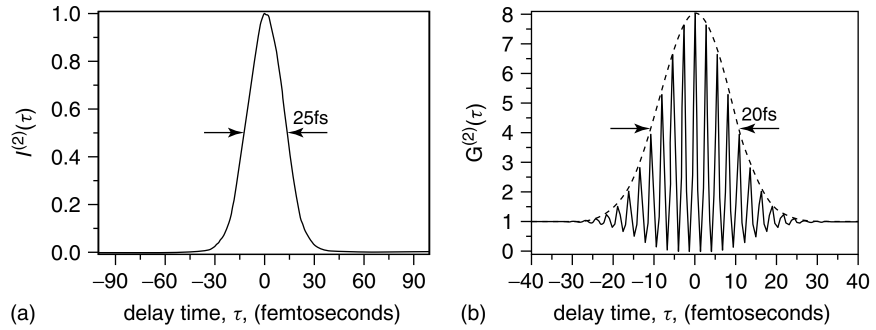

Fig. 21.2 (a) Intensity autocorrelation, without background, showing a FWHM (full width at half maximum) of 25 fs. This corresponds to a pulse with time duration of 16.3 fs, assuming a hyperbolic secant squared pulse profile. (b) Interferometric autocorrelation showing the optical field oscillations. This corresponds to a pulse of 14.8 fs.

of such a measurement can be seen in Figure 21.2(a). To recover the pulse duration, it is necessary to fit the measured data by assuming some functional form for the intensity. Usually ultrashort pulses originating from mode-locked lasers have a temporal shape described by a squared hyperbolic secant function (Jean-Claude and Rudolph, 1996). For a given spectral bandwidth, the attainable theoretical shortest temporal pulse is called *Fourier transform limited* (or simply *transform limited*). For such pulses, the spectral phase difference between the wavelengths that compose the spectrum is constant or equal to zero. This can be tested using the expression: $\Delta\nu\Delta\tau_P \geq c_B$, where $\Delta\nu$ is the spectral bandwidth of the pulse (in Hertz), $\Delta\tau_P$ is the temporal duration, and c_B is a constant that is determined by the model assumed to fit the temporal intensity autocorrelation. For Gaussian and squared hyperbolic secant functions, c_B is equal to 0.44 and 0.31, respectively. The equality in the above expression is achieved for transform limited pulses (Rulliere, 1998).

For the shortest pulses, it is found that transmission of the pulse through any dense medium leads to pulse broadening. This naturally arises from the normal dispersion of the medium, which causes the red portion of the broadband laser spectrum to travel faster than the blue, creating a spread in time (a chirp) (Jean-Claude and Rudolph, 1996). Chirped pulse amplifiers exploit this phenomenon. For high time resolution optical experiments, a correction for this effect must be made. To first order, this is achieved using a simple prism pair. Routing the chirped beam twice through the prism pair, oriented at Brewster's angle, causes the red light to travel further than the blue (negative dispersion). By carefully matching the positive and negative dispersion by controlling the prism separation, the experimenter can deliver the shortest pulses to the sample.

21.4
Ultrafast Experiments

21.4.1
Transient Absorption

This experiment is essentially an extension of the flash photolysis experiment developed by Porter and coworkers (Porter and Wilkinson, 1961) into the ultrafast time domain. It shares with that method the principle of optical excitation of the sample by one pulse and then measurement of the entire spectrum as a function of time with a second broadband pulse. In accessing the subpicosecond time domain, one encounters the same problem as was mentioned in Section 21.3, that no conventional electronic detector is capable of real-time measurements on the subpicosecond timescale. Thus the requirement for the transient absorption experiment is an ultrafast pump and an ultrafast probe pulse, and the latter should have as broad a spectrum as possible. A broad spectrum with an ultrafast temporal width may be generated by the simple expedient of focusing an intense titanium sapphire laser pulse into a transparent medium (a water cell works well). Through a highly nonlinear interaction called self-phase modulation, a fraction of this incident light is converted into a broad band source stretching from the UV to the near IR with a temporal width as short as the input pulse (Shen, 1984).

The pump and probe pulses are then combined in essentially the same geometry as was shown for the pulse width measurement (Figure 21.1), with the sample taking the place of the nonlinear crystal. The pump pulse strikes the sample at a time defined as $t = 0$, where it is absorbed, transferring population from the ground to the excited electronic state. In general, the excited state will have a distinct absorption spectrum. The spectrally broad probe pulse is incident on the same point in the sample at a time τ later, where τ is controlled by the path length difference introduced between the pump and probe paths. On transmission through the sample the probe beam spectrum is measured by a polychromator. For the most accurate measurements, a correction must be made for the dispersion which causes the red and blue components of the probe spectrum to travel at slightly different velocities, thus reducing the time resolution.

Typically, the change in transmission induced by the pump pulse is small – a small percentage at most. To obtain reliable measurements, it is desirable to record an identical reference spectrum taken when the pump pulse is blocked. From these two measurements, a difference spectrum may be created, and the reference spectrum can be used to normalize out intensity fluctuations. The logarithm of the resulting ratio yields the transient optical density difference spectrum, where negative peaks correspond to bleaching of the ground state and positive peaks show transient absorption spectra of newly created states, which may be formed either during the excitation or during subsequent chemical reactions. The transient absorption method has been used by many groups over the years to reveal photo-induced processes in molecules ranging from simple dissociation or ring opening reactions to the dynamics of the photosynthetic system. Changes in optical densities lesser than 10^{-4} can be measured.

21.4.2
Ultrafast Fluorescence Up-Conversion

Fluorescent molecules are widely used as probes of natural and synthetic materials for numerous reasons: fluorescence is very sensitive to its environment; the probe can be introduced to the medium in a site specific fashion; it may be detected with high (single molecule) sensitivity; it affords a noncontact method of probing the material (Lakowicz, 2006). Time resolved fluorescence has long been used to add an additional dimension to fluorescence spectroscopy (Maroncelli and Fleming, 1987). The classical time-correlated single photon counting method has been refined to the extent that excited state decay times of tens of picoseconds can be resolved (Phillips and O'Connor, 1983). However, for true ultrafast time resolution, the fluorescence up-conversion method must be used (Fleming, 1986).

The up-conversion method is essentially an ultrafast sampling of the temporal profile of the sample fluorescence. The experimental geometry is shown in Figure 21.3 (Shah, 1988).

Two ultrafast laser pulses are required, exactly correlated in time. Often the fundamental and second harmonic of the laser are used. The higher energy pulse electronically excites the sample, which relaxes through fluorescence decay at an energy ν_f. The fluorescence is focused into a nonlinear crystal where it is mixed with the second ultrafast laser pulse of frequency ν_p. The nonlinear

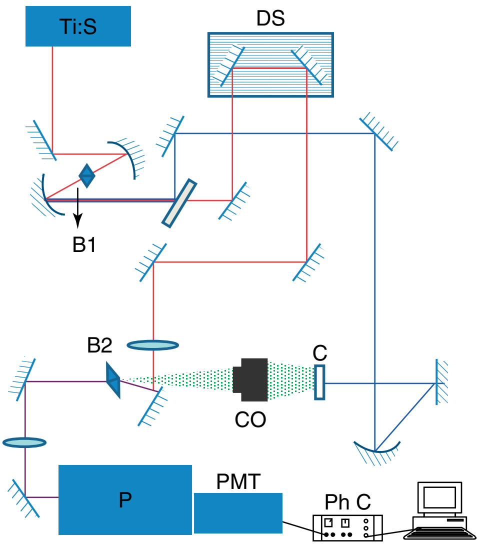

Fig. 21.3 Femtosecond fluorescence up-conversion experimental setup: Ti : S, titanium–sapphire laser; B1, 50-µm BBO crystal; B2, 100-µm BBO crystal; DS, delay stage; CO, collection optics; C, cell containing sample; P, polycromator; PMT, photomultiplier tube; Ph C, photon counter.

interaction in the crystal generates the sum frequency $\nu_{\text{sum}} = \nu_f + \nu_p$ in the phase matching direction. This signal can clearly only be generated when both fluorescence and laser pulse are present in the crystal, and its intensity is a product of their two instantaneous intensities. Thus for constant laser pulse energy, the nonlinear interaction samples the intensity of the fluorescence at the instant of the arrival of the second pulse. By scanning the arrival time of the pulse and measuring the sum frequency intensity as a function of time, the fluorescence decay profile is mapped out. As an example, Figure 21.4 presents a semilog plot of the up-converted fluorescence intensity relaxation of an aqueous solution of the dye molecule auramine O (van der Meer *et al.*, 2000). The signal can be described by a sum of two exponential decays.

As in all ultrafast experiments, the highest time resolution is only achieved if the dispersion is minimized. For up-conversion, this requires independent dispersion compensation in the excitation and up-converting pulses, and as far as possible all reflective optics should be used (Joo and Rhee, 2005).

Fluorescence up-conversion is a particularly powerful tool as it allows detailed studies of a diverse range of phenomena. Excited state reactions (isomerization, electron and proton transfer) (Kang *et al.*, 1990; Todd *et al.*, 1990) are among the simplest known and their dynamics have been characterized in great detail through fluorescence. Similarly, the dynamics of solvation can be measured from the temporal evolution of the fluorescence spectrum (Maroncelli and Fleming, 1987). Such studies have provided very detailed views of condensed phase dynamics, and have been used as benchmarks to test molecular dynamics simulations. Having been well characterized in solution, similar experiments are being conducted in complex media including living cells.

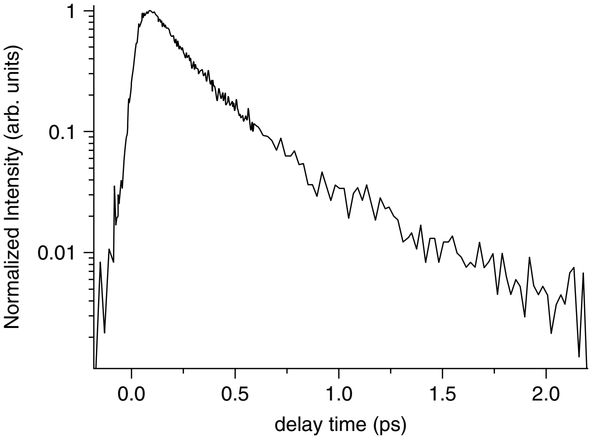

Fig. 21.4 Up-converted signal intensity showing the fluorescence relaxation of dye auramine O in water solution.

21.4.3
Polarization Spectroscopy

A number of techniques that relate spectroscopic information to the polarization properties of electromagnetic radiation are known as *polarization spectroscopy* (Kano and Levenson, 1988). In general, the initial polarization state of the light source is well defined. This source interacts with an anisotropic material resulting in a new polarization state which is analyzed. The anisotropy can be either inherent to the medium (e.g., a crystalline or liquid crystal material) or externally imposed (e.g., the Kerr effect in the presence of strong electric field). Within the realm of ultrafast spectroscopy, a long established and widely applied time resolved technique is the optical Kerr effect (OKE) (Smith and Meech, 2002). In this account, we focus on the OKE technique applied to transparent media, and its analog applied to absorbing media.

One great appeal of the OKE technique is that it measures the low-frequency Raman spectrum (0–500 cm^{-1}) of the medium with extremely high signal-to-noise ratio. This spectrum contains detailed information about the medium dynamics. The OKE signal (Figure 21.5 shows the usual experimental setup) originates from an intense linearly polarized optical pulse, which interacts with an initially isotropic sample (Lotshaw *et al.*, 1995). This pulse, called the *pump*, induces a transient anisotropy through the molecular polarizability, which is probed by a second, weak, time-delayed pulse, incident at the same point in the sample. The probe pulse is linearly polarized and has its plane of polarization at 45° with respect to the pump pulse. The pump-induced anisotropy depolarizes the probe pulse, which emerges from the sample slightly elliptically polarized. A polarizer, crossed with the plane of polarization of the probe pulse, is placed in front of the detector. The pump-induced depolarization causes a fraction of the probe pulse to reach the detector (homodyne signal). The signal is measured as a function of delay time between the pump and probe pulses and so

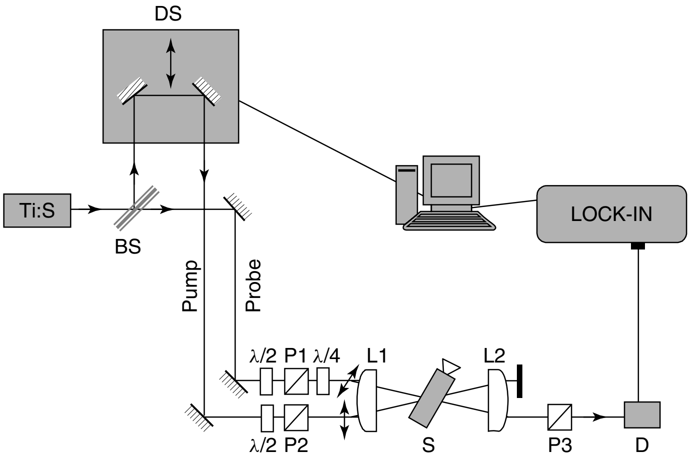

Fig. 21.5 OKE typical experimental setup. Ti : S, Ti : sapphire femtosecond laser; BS, beam splitter; DS, delay stage; P1-3, polarizers; L1-2, lenses; S, sample; and D, detector.

the relaxation of the induced anisotropy in the sample is measured. For a homodyne measurement, the detected signal is quadratically and linearly proportional to the pump and probe pulse intensities, respectively. Additionally, the measured signal is quadratically proportional to the impulse response function of the material, $R_{ijkl}(t)$ (discussed further in Section 21.4.4 below). The response function is related to the frequency-dependent third-order nonlinear susceptibility, $\chi^{(3)}_{ijkl}(\omega)$, through a Fourier transform relationship, and contains both real (dispersive) and imaginary (resonant) parts.

To improve the signal-to-noise ratio and to avoid the complexity of analyzing a quadratic signal, a heterodyned measurement is employed (Kano and Levenson, 1988). This is achieved by the addition of a local oscillator (LO) to the OKE signal. The LO is derived from the probe pulse in either of two ways: (i) by a slight rotation of the analyzer polarizer (P3), which introduces a component *in phase* with the OKE signal; (ii) by the introduction of a quarter wave plate (λ/4) in the probe beam with its fast axis initially aligned with the probe polarization; after a slight rotation of P1 (generally $\leq 1^\circ$) a small component *in quadrature* with the homodyne OKE signal will leak through the analyzer polarizer. The signal measured by the square law detector is:

$$I_D = I_{\mathrm{LO}} + I_S + \frac{nc}{8\pi}\left(E_S^* E_{\mathrm{LO}} + E_S E_{\mathrm{LO}}^*\right) \tag{21.4}$$

where E_i and I_i are the field and the intensity of the LO or homodyne OKE signal field, respectively. The term in brackets is the *heterodyne term*, which scales linearly with $R_{ijkl}(t)$. The LO field amplitude is set to produce a heterodyne signal much larger than the homodyne intensity, but small enough to avoid detector saturation. The LO signal is easily eliminated from measurement using lock-in detection. It is important to note that the real and imaginary contributions to the signal field, E_S, are associated, respectively, with the imaginary (dichroism) and real

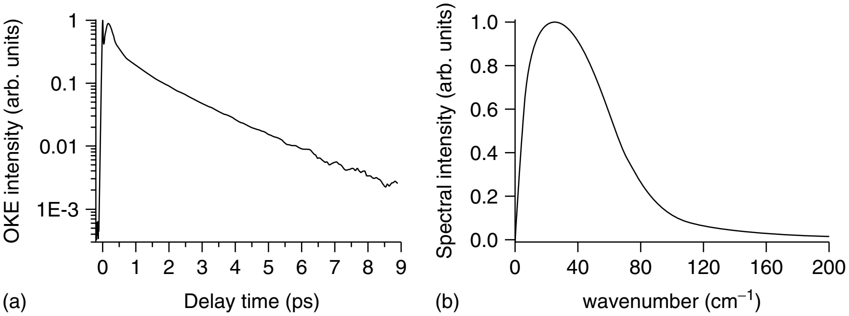

Fig. 21.6 (a) OKE signal for carbon disulfide (CS_2) on a semilog plot. (b) Spectral intensity content of CS_2 OKE signal after subtraction of the diffusive exponential component.

(birefringence) parts of the material response function, $R_{ijkl}(t)$. These may be measured separately depending on the phase introduced in the local oscillator field, E_{LO}.

When the sample is transparent, the real (birefringence) part of the response dominates. The data may be analyzed in either the time or the frequency domain. The latter are accessed through a Fourier transform deconvolution procedure resulting in the Raman spectral density (Lotshaw *et al.*, 1995). Figure 21.6 shows a typical OKE signal for carbon disulfide (CS_2) liquid at room temperature.

CS_2 has one the largest OKE signals, due to its high polarizability anisotropy, and shows many features shared with various other molecular liquids for which OKE measurements have been performed (Castner *et al.*, 2007; Cong *et al.*, 1995; Fourkas, 2002; Friedman and She, 1993; Heisler *et al.*, 2005; Hunt *et al.*, 2007; Hunt and Meech, 2004). At time zero, there is a symmetric instantaneous response which follows the laser pulse autocorrelation. This signal arises from the electronic hyperpolarizability. The nuclear dynamics response of most interest appears with a risetime (around 100 fs) due to the inertial molecular motion that cannot follow the impulsive force exerted by the strong ultrashort laser pump field. The signal then shows a complex subpicosecond relaxation followed by a picosecond time scale, exponential response (Figure 21.6a). This component is well described by a Stokes–Einstein–Debye model of diffusive orientational relaxation (McMorrow *et al.*, 1988). The subpicosecond decay component is usually called *nondiffusive* but scales with the diffusive relaxation (Loughnane *et al.*, 1999). Its origin remains a matter of discussion. On an ultrafast timescale, the single-molecule contribution will take the form of a hindered molecular reorientation or librational motion, which is well fit by a molecule rattling in a cage model. This signal relaxes approximately as a Gaussian function but usually the analysis is made in the frequency domain to avoid model-dependent fitting (Figure 21.6b). Such detailed pictures of liquid state molecular dynamics provide data against which to test both theories and molecular dynamics simulations of the liquid state. In more complex fluids, additional low-frequency intramolecular modes may contribute to the Raman spectral density, and these may be the characteristic of macromolecular structure (Hunt and Meech, 2004, 2003).

When the pump and probe pulses are resonant with a strong electronic transition, then the transient dichroism (imaginary component of $R_{ijkl}(t)$) dominates the response, which may be selectively measured by using an in-phase LO. If the absorption is due to a molecular solute, then the time-dependent signal probes both the solute orientational relaxation and the ground state recovery (because both will ultimately lead to a recovery of the initial isotropic distribution). The experiment can then be used to access information on both molecular orientational motion and excited state kinetics, and has been applied to diverse samples (Cho *et al.*, 1993; Waldeck *et al.*, 1981).

21.4.4
Nonlinear Optics and Ultrafast Spectroscopy

It is apparent that the experiments described above report on multiple interactions of the laser pulses with the sample. Thus it is evident that a natural theoretical picture of such interactions will involve a time domain description invoking nonlinear optics (Mukamel, 1995). It is in general possible to separate optical measurements into linear and nonlinear regimes according to the electric field $\mathbf{E}(t)$ power-law dependence of the process. In such measurements, to properly calculate the signal, one has to start with the Maxwell equations. In these, the only material quantity that appears as a source is given by the optical polarization $\mathbf{P}(t)$ induced by some applied external electric field $\mathbf{E}(t)$. Therefore, a complete knowledge of the optical polarization is essential for the interpretation of any time or frequency domain spectroscopic measurement. Usually a constitutive relation is used to describe the induced polarization in a medium when an electric field is applied. The polarization may be expanded as a power series in the electric field vector (Boyd, 2003):

$$\mathbf{P}(t) = \boldsymbol{\chi}^{(1)}\mathbf{E}(t) + \boldsymbol{\chi}^{(2)}\mathbf{E}(t)\,\mathbf{E}(t) + \boldsymbol{\chi}^{(3)}\mathbf{E}(t)\,\mathbf{E}(t)\,\mathbf{E}(t) + \cdots \tag{21.5}$$

where $\boldsymbol{\chi}^{(n)}$ are material susceptibility coefficients, which in general are tensors (Butcher and Cotter, 1990). As a consequence, the orientation of the induced polarization may be different from that of the applied field. Therefore, it is possible to rewrite the polarization as:

$$\mathbf{P}(t) = \mathbf{P}^{(1)}(t) + \mathbf{P}_{\mathrm{NL}}(t) \tag{21.6}$$

where $\mathbf{P}^{(1)}(t)$ is the linear polarization, accounting for processes such as absorption, reflection, refraction, and so on, and $\mathbf{P}_{\mathrm{NL}}(t)$ is the nonlinear polarization describing higher order processes such as second harmonic generation, optical Kerr effect, two-photon absorption, self-phase modulation, and so on. For time resolved experiments, a better approach to describing optical measurements is through response functions $R(t)$, which have their counterpart in the frequency domain description through the susceptibilities $\chi(\omega)$. The relation between these quantities is given by a Fourier transform:

$$\chi(\omega) = \int_{-\infty}^{\infty} dt\; R(t)e^{i\omega t} \tag{21.7}$$

The response function formalism can be applied to a broad range of linear and nonlinear optical measurements differing in terms of the applied temporal sequence of pulses, frequencies or propagation direction (wavevectors) (Mukamel, 1995). Thus, this formalism enables one to describe and calculate the signals expected for different ultrafast experiments and ultimately compare their information content.

The response function contains information on how a system alters in response to an external applied perturbation. It has been shown that if changes involve small departures from equilibrium, then the equilibrium fluctuations dictate the nonequilibrium response. Thus knowledge of the equilibrium dynamics is useful for predicting nonequilibrium processes.

The polarization at a given time t is related to the applied electric field at all earlier times and can be written, for first and second order, as

$$P_i^{(1)}(t) = \int_{-\infty}^{t} dt_1 R_{ij}^{(1)}(t, t_1) E_j(t_1) \quad (21.8)$$

$$P_i^{(2)}(t) = \int_{-\infty}^{t} dt_2 \int_{-\infty}^{t_2} dt_1 R_{ijk}^{(2)}(t, t_1, t_2) \times E_j(t_1) E_k(t_2) \quad (21.9)$$

and for the nth-order as

$$P_i^{(n)}(t) = \int_{-\infty}^{t} dt_n \ldots \int_{-\infty}^{t_3} dt_2 \int_{-\infty}^{t_2} dt_1 \times R_{ijk\ldots m}^{(n)}(t, t_1, t_2, \ldots, t_n) \times E_j(t_1) E_k(t_2) \ldots E_m(t_n) \quad (21.10)$$

with the convention of summation over repeated indices. The newly defined nth-order response function, $R^{(n)}$, is a tensor of rank n + 1, and a real and causal function of time (Mukamel, 1995). Also, the response is a function of the relative time between perturbation and observation, that is, $R^{(n)}(t, t_0) = R^{(n)}(t - t_0)$. Ordering the fields and labeling the relative time as in Figure 21.7, it is possible to rewrite the expressions for the polarization in a more intuitive fashion as

$$P_i^{(1)}(t) = \int_0^{\infty} d\tau_1 R_{ij}^{(1)}(\tau_1) E_j(t - \tau_1) \quad (21.11)$$

$$P_i^{(2)}(t) = \int_0^{\infty} d\tau_2 \int_0^{\infty} d\tau_1 R_{ijk}^{(2)}(\tau_1, \tau_2) \times E_j(t - \tau_2) E_k(t - \tau_2 - \tau_1) \quad (21.12)$$

$$P_i^{(n)}(t) = \int_0^{\infty} d\tau_n \ldots \int_0^{\infty} d\tau_2 \int_0^{\infty} d\tau_1 \times \begin{pmatrix} R_{ijk\ldots m}^{(n)}(\tau_1, \tau_2, \ldots, \tau_n) \\ E_j(t-\tau_n) E_k(t-\tau_n-\tau_{n-1}) \\ \times \ldots E_m(t-\tau_n-\tau_{n-1} \\ \times \ldots - \tau_2 - \tau_1 \end{pmatrix} \quad (21.13)$$

The optical electric field couples with the material via the microscopic charge distribution. As mentioned before, for spectroscopic measurements, the signal

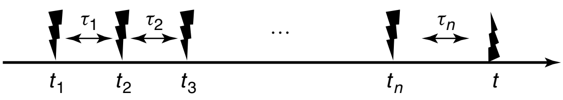

Fig. 21.7 Electric fields time ordering and resulting polarization.

is determined by the macroscopic polarization $\mathbf{P}(t)$, which in turn, is given in terms of the average over an ensemble of particles contained in a volume V, of the expectation value of the dipole operator $\boldsymbol{\mu}$:

$$\mathbf{P}(t) = \frac{1}{V}\overline{\langle\mu(t)\rangle} = \frac{1}{V}\mathrm{Tr}\{\boldsymbol{\mu}\rho(t)\} \quad (21.14)$$

In the above definition, the dipole operator is given by the instantaneous positions of all charged particles of the ensemble contained in volume V (nuclei and electrons):

$$\boldsymbol{\mu} = \sum_i e_i \mathbf{r}_i \quad (21.15)$$

The last term on the right hand side of Eq. (21.14) introduces the density matrix ($\rho(t)$) formalism to calculate the polarization, where Tr is the trace over the matrix representation. The density matrix evolution is determined by the Liouville equation:

$$\frac{d\rho}{dt} = -\frac{\mathrm{i}}{\hbar}[H_I(t), \rho] \quad (21.16)$$

Here we are assuming the interaction picture description where $H_I(t)$ accounts for the light-matter time-dependent interaction, which in the electric dipole approximation can be written as

$$H_I(t) = -\boldsymbol{\mu} \cdot \mathbf{E}(t) \quad (21.17)$$

The general solution for the evolution equation can be written as:

$$\rho(t) = \rho(t_0) - \frac{\mathrm{i}}{\hbar}\int_{t_0}^{t} dt_1 [H_I(t_1), \rho(t_1)] \quad (21.18)$$

It is not possible to solve this equation exactly. The procedure usually adopted is to expand the density matrix operator and then to solve the evolution equation iteratively.

$$\rho(t) = \rho^{(0)}(t) + \rho^{(1)}(t) + \rho^{(2)}(t) + \ldots \quad (21.19)$$

Applying this perturbative approach, solutions for the different orders are

$$\rho^{(0)}(t) = \rho(t_0) = \rho_{\mathrm{eq}} \quad (21.20)$$

$$\rho^{(1)}(t) = -\frac{\mathrm{i}}{\hbar}\int_{-\infty}^{t} dt_1 \left[H_I(t_1), \rho_{\mathrm{eq}}\right] \quad (21.21)$$

$$\rho^{(2)}(t) = \left(-\frac{\mathrm{i}}{\hbar}\right)^2 \int_{-\infty}^{t} dt_2 \int_{-\infty}^{t_2} dt_1 \times \left[H_I(t_2), \left[H_I(t_1), \rho_{\mathrm{eq}}\right]\right] \quad (21.22)$$

and for the nth-order:

$$\rho^{(n)}(t) = \left(-\frac{\mathrm{i}}{\hbar}\right) \int_{-\infty}^{t} dt_n \ldots \int_{-\infty}^{t_3} dt_2 \times \int_{-\infty}^{t_2} dt_1 [H_I(t_n), [H_I(t_{n-1}), \ldots [H_I(t_3), [H_I(t_2), [H_I(t_1), \rho_{\mathrm{eq}}]]] \ldots]] \quad (21.23)$$

The system, before any interaction, is in the equilibrium state; therefore, the assumption $t_0 = -\infty$ may safely be made. Again, to present the expressions in a more physical manner, it is helpful to perform a change of variables so that the time intervals between successive interactions of the electric field with the dipole moment appear explicitly. As an example, we present the expression for the third-order polarization, after developing the commutator terms of Eq. (21.23) and inserting them into Eq. (21.14), resulting in

$$P_i^{(3)}(t) = \frac{1}{V}\left(-\frac{\mathbf{i}}{\hbar}\right)^3 \int_0^\infty d\tau_3 \int_0^\infty d\tau_2 \times \int_0^\infty d\tau_1 \left(\begin{array}{l} \mathrm{Tr}\left\{[[[\mu_i(\tau_1+\tau_2+\tau_3), \right. \\ \quad \mu_l(\tau_1+\tau_2)], \mu_k(\tau_1)], \\ \quad \left. \mu_j(0)]\rho_{\mathrm{eq}}\right\} \\ E_j(t-\tau_3)E_k(t-\tau_3-\tau_2) \\ \quad \times E_l(t-\tau_3-\tau_2-\tau_1) \end{array}\right) \tag{21.24}$$

From this expression, the third-order response function is given by

$$R_{ijkl}^{(3)}(\tau_3, \tau_2, \tau_1) = \theta(\tau_3,\ \tau_2,\ \tau_1)\left(-\frac{\mathbf{i}}{\hbar}\right)^3 \times \mathbf{Tr}\left\{\left[\,[[\mu_i(\tau_1+\tau_2+\tau_3), \mu_l(\tau_1+\tau_2)], \mu_k\ (\tau_1)]\,, \mu_j(0)\right]\rho_{\mathrm{eq}}\right\} \tag{21.25}$$

where $\theta(\tau)$ is the Heaviside function used to impose the causality condition. This expression makes the connection between the microscopic material quantity (the dipole moment which couples to the electric field) and the response function measured through the macroscopic induced polarization. It can be further particularized to a given experiment by choosing the configuration of the applied electric fields and also the particular multipolar moment which is interacting with the field (*i.e.*, fixed dipole moment, polarizability, hyperpolarizability, etc). By working out the commutator expressions, it is possible to rewrite the response functions as

$$R_{ijkl}^{(3)}(\tau_3, \tau_2, \tau_1) = \theta(\tau_3)\theta(\tau_2)\theta(\tau_1) \times \left(-\frac{\mathbf{i}}{\hbar}\right)^3 \sum_{\alpha}^{4} R_\alpha(\tau_3, \tau_2, \tau_1) \times -R_\alpha^*(\tau_3, \tau_2, \tau_1) \tag{21.26}$$

where

$$R_1(\tau_3, \tau_2, \tau_1) = \mathrm{Tr}\left\{\mu_i(\tau_1+\tau_2+\tau_3) \times \mu_l(\tau_1+\tau_2)\mu_k(\tau_1) \times \mu_j(0)\rho_{\mathrm{eq}}\right\} \tag{21.27}$$

$$R_2(\tau_3, \tau_2, \tau_1) = \mathrm{Tr}\left\{\mu_j(0)\mu_l(\tau_1+\tau_2) \times \mu_i(\tau_1+\tau_2+\tau_3) \times \mu_k(\tau_1)\rho_{\mathrm{eq}}\right\} \tag{21.28}$$

$$R_3(\tau_3, \tau_2, \tau_1) = \mathrm{Tr}\left\{\mu_j(0)\mu_k(\tau_1) \times \mu_i(\tau_1+\tau_2+\tau_3)\mu_l \times (\tau_1+\tau_2)\rho_{\mathrm{eq}}\right\} \tag{21.29}$$

$$R_4(\tau_3, \tau_2, \tau_1) = \mathrm{Tr}\left\{\mu_k(\tau_1)\mu_l(\tau_1+\tau_2) \times \mu_i(\tau_1+\tau_2+\tau_3) \times \mu_j(0)\rho_{\mathrm{eq}}\right\} \tag{21.30}$$

The complex terms can easily be worked out in the same fashion.

Third-order nonlinearities describe many of the coherent nonlinear experiments commonly used in research laboratories worldwide: pump-probe, transient grating, photon echoes, coherent antistokes Raman spectroscopy (CARS), degenerate four-wave mixing are some of the most important of these. These experiments are described by some or all of the eight correlation functions that contribute to $R_{ijkl}^{(3)}(\tau_3, \tau_2, \tau_1)$. This shows how complete and general the response formalism can be, and how it can be applied to essentially any ultrafast experiment (Mukamel, 1995). Roughly speaking, once the configuration of electric fields used in the experiment is established, one can refer to these expressions to determine the measured signal outcome. The next step would be to include the relaxation terms involved in a given sample system. This can be done with various

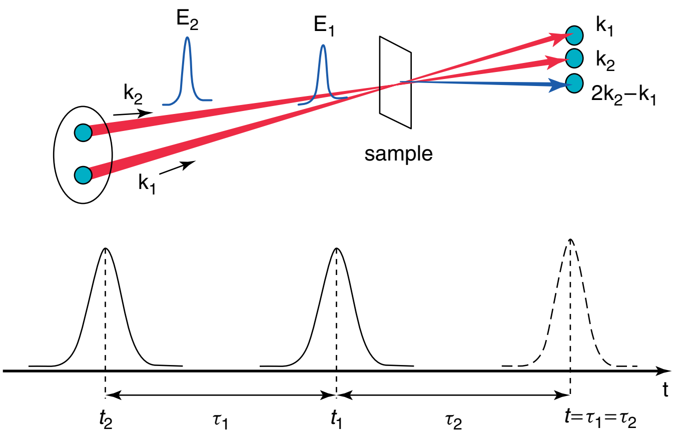

Fig. 21.8 Two-pulse photon echo time ordering and spatial beam geometry. (Adapted from Andrei Tokmakoff, 5.74 Introductory Quantum Mechanics II, Spring 2007. (MIT OpenCourseWare: Massachusetts Institute of Technology). http://ocw.mit.edu/OcwWeb/Chemistry/5-74Spring-2007/CourseHome. Accessed Oct. 1, 2008.)

degrees of complexity, and the outcome depends somewhat on the nature of the sample under study. A number of examples exist in the literature (Mukamel, 1995).

21.4.5
Photon Echoes

The photon echo technique is an interesting example of the kind of multipulse optical experiment, which is currently being developed in ultrafast spectroscopy. The original experiments were an important demonstration of coherent optical phenomena (Kurnit *et al.*, 1964). Measurements on the picosecond timescale revealed the photon echo as being an important tool in molecular spectroscopy, particularly, in allowing the direct measurement of the homogeneous optical lineshape free of inhomogeneous broadening (de Boeij *et al.*, 1998). In the original two-pulse photon echo, two pulses are incident on the sample at times t_1 and t_2 (Figure 21.8).

At a time $\tau_1 = t_1 - t_2$, the sample emits a signal – the photon echo – at the same frequency as the input pulses and in the phase matched direction, $\mathbf{k}_{\mathrm{PE}} = \mathbf{2k}_2 - \mathbf{k}_1$. The analogy with spin echoes in NMR is obvious and quite appropriate. By scanning the pulse separation and measuring the echo intensity, the homogeneous lifetime of the transition can be measured. A further level of sophistication is the three pulse photon echo (Cho *et al.*, 1992). Figure 21.9 shows the time orderings of the pulses and the emitted signal, related to the third-order nonlinear polarization, $\mathrm{P}^{(3)}(t')$, together with the 'box' geometry usually applied. The times τ and T denote the center to center distances between the pulse pairs E_1, E_2 and E_2, E_3, respectively. Also, t_1, t_2, and t_3 denote field–matter interaction points related to the response function

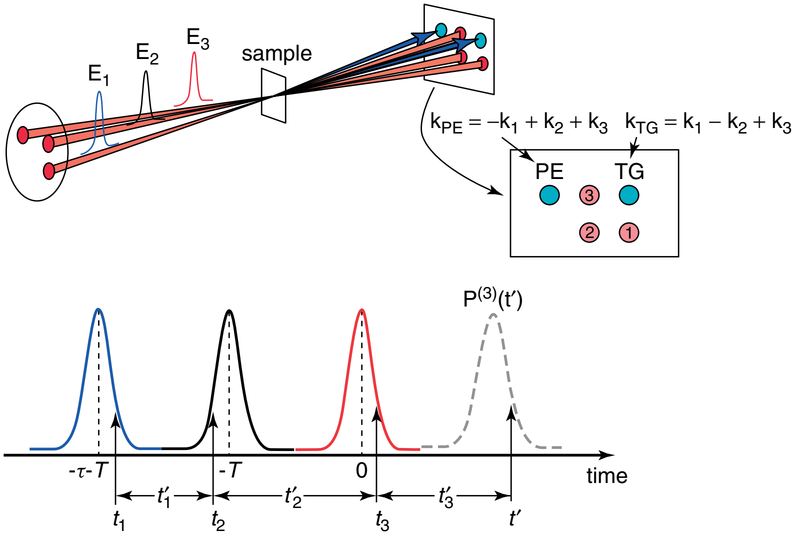

Fig. 21.9 Three pulse photon echo time ordering and spatial beam geometry. Also shown is the box geometry highlighting the phase matched direction for the photon echo signal (PE) and the transient grating signal (TG). (Adapted from Andrei Tokmakoff, 5.74 Introductory Quantum Mechanics II, Spring 2007. (MIT OpenCourseWare: Massachusetts Institute of Technology) http://ocw.mit.edu/OcwWeb/Chemistry/5-74Spring-2007/CourseHome. Accessed Oct. 1, 2008.)

formalism Eq. (21.10), while t'_1, t'_2, and t'_3 denote the relative delays between the interaction points. In this experiment, there are three pulses involved and two delays to be controlled. Changing the delays independently yields quite different dynamic information.

Varying t'_1 yields the homogeneous lifetime, while scanning t'_2 yields the population relaxation time. In analogy with NMR, the measured times are then T_2 and T_1, respectively, although the factors influencing the optical relaxation times are quite different to the nuclear spin case (and the relaxation times in molecules are many orders of magnitude faster). The phase matching direction for the emitted photon echo signal is now given by $\mathbf{k}_{\mathrm{PE}} = -\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3$, as illustrated in Figure 21.9. Also, when $t_1 - t_2 = 0$ and measuring the wave vectors phase matched beam in the direction given by $\mathbf{k}_{\mathrm{TG}} = \mathbf{k}_1 - \mathbf{k}_2 + \mathbf{k}_3$, the experiment is analogous to transient grating scattering. The photon echo and transient grating techniques are also known as *rephasing and non-rephasing methods*, respectively. In terms of the response function contributions (Eqs (21.27)–(21.30)), it is possible to show that the terms that describe the photon echo signal are given by the sum of $R_2 + R_3$ and for the transient grating the terms that contribute are $R_1 + R_4$. Again, this illustrates the generality and completeness of the response functions formalism (Mukamel, 1995).

Unfortunately, as discussed in literature, the photon echo intensity measurements as a function of the delays

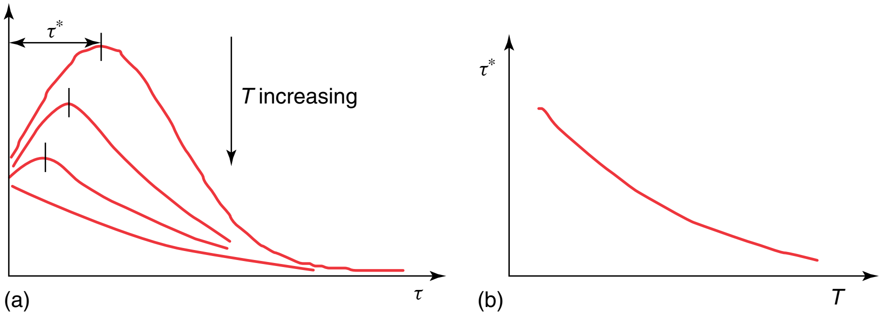

Fig. 21.10 (a) Drawing representing the evolution of the photon echo signal as the population time, T, is increased. (b) Plotting the photon echo peak against T results in the echo peak shift measurement. (Adapted from Andrei Tokmakoff, 5.74 Introductory Quantum Mechanics II, Spring 2007. (MIT OpenCourseWare: Massachusetts Institute of Technology) http://ocw.mit.edu/OcwWeb/Chemistry/5-74Spring-2007/CourseHome. Accessed Oct. 1, 2008.)

t_1' and t_2' provide no direct information on the system-bath interaction dynamics, unless there is a clear and strict separation of timescales as, for example, in the Bloch limit (Bloch, 1946; Nibbering *et al.*, 1994). Usually when working with solutions, the dynamics cannot be classified simply as homogeneous or inhomogeneous. Recently for a probe parameter that could follow the dynamics of the frequency correlation function was sought. An apparently excellent candidate is the measurement of the echo peak shift (Desilvestri *et al.*, 1984; Weiner *et al.*, 1985). With the advent of amplified laser systems and optical parametric oscillator/amplifiers, which in conjunction are able to deliver pulses shorter than 20 fs in a broad wavelength region, the subject was revived and the echo peak shift technique has attracted new interest. In addition, very recently, it has been shown that there is a direct connection between the echo peak shift measurement and the amplitude of the frequency correlation function fluctuations due to the system-bath interaction (Fleming and Cho, 1996). In the three pulse echo peak shift (3 PEPS) experiment, the integrated photon echo intensity is measured for a fixed population delay time, T, while scanning the coherence delay time, τ. The shift of the photon echo maximum with respect to zero delay along the τ axis constitutes the observable, the so-called echo peak shift. It was demonstrated that a plot of the echo peak shift as a function of waiting time T, (Figure 21.10) tracks the frequency correlation function, which carries information about the system-bath interaction (de Boeij *et al.*, 1996). Such experiments represent a powerful tool for unraveling optical dynamics in complex condensed phase systems.

21.5
The Future

The technology and the theory of ultrafast spectroscopy have entered into a mature phase. The future now would appear to lie in establishing the range and power of these new methods. One particularly striking example currently under intense investigation is multidimensional ultrafast spectroscopy. In preceding sections, the analogy of optical and NMR measurements was noted. Extending this idea to the multipulse experiments described above suggests the possibility of a suite of ultrafast experiments to match those associated with multipulse NMR. Numerous researchers are investigating the possibility of exploiting two-dimensional experiments, characterized my multiple pulses and time delays (of which 3PEPS is one example) to determine molecular structural evolution on an ultrafast time scale. In many respects, this is the holy grail of molecular science – a method that demonstrates where the nuclei are during the course of a chemical reaction. Important progress is being made, particularly, in terms of two-dimensional vibrational spectroscopy (Demirdoven *et al.*, 2004; Khalil *et al.*, 2003; Wright, 2002; Zheng *et al.*, 2007).

23.1
Introduction

The use of optical second harmonic generation (SHG) measurement for the exploration of dielectric polarization and related surface phenomena is described. A classification of materials using orientational order parameters shows that a surface monolayer is the most generalized system for discussing SHG enhancement from materials, and a theory developed for a monolayer system is broadly extended to other systems such as bulk system materials. On the basis of this background, SHG enhancement from an organic monolayer system is described with a schematic illustration of a typical experimental system. It is shown that SHG is generated from surface monolayers due to their noncentrosymetric structure and is available for the determination of orientational order of surface layers, and so on. It is also shown that SHG is generated from layers with centrosymmetric structure that are subjected to a high static electric field, owing to induced effective dipoles. Results show that enhanced SHG is available for probing excess surface charges. In addition, optical sum-frequency generation (SFG) is briefly described, and we show that this can be available as spectroscopic method for detecting the motion of molecules at the molecular level.

23.2
Order Parameters and Surface Layer

The orientational order parameter is specially important to specify the dielectric property of surface layers that generate SHG and SFG. Material systems composed of rod molecules are classified using orientational order parameters S_n $(n = 1, 2, 3)$ defined by the thermodynamic average of the Legendre polynomials, $P_n(\cos\theta)$ $(n = 1,\ 2,$ and $3)$, of the orientational angle θ of molecules with respect to the surface. For isotropic bulk materials, rod molecules are randomly distributed in space. Thereby $S_1 = \langle P_1(\cos\theta)\rangle = \langle\cos\theta\rangle = 0$, $S_2 = \langle P_2(\cos\theta)\rangle = \langle(3\cos^2\theta - 1)/2\rangle = 0$, and $S_3 = \langle P_3(\cos\theta)\rangle = \langle(5\cos^3\theta - 3\cos\theta)/2\rangle = 0$. On the other hand, orientational direction of molecules is restricted for ordered materials. For example, constituent molecules in nematic phase bulk liquid crystals (LCs) are totally distributed in "up" and "down" directions, without distinction between them. Therefore, $S_1 = 0$, $S_3 = 0$, but $S_2 \neq 0$. Interestingly, for a monolayer composed

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

of rod molecules, all molecules point upward owing to symmetry breaking. Therefore, S_1, S_2, $S_3 \neq 0$. This simple classification suggests that the physical properties of materials are expressed in terms of orientational order parameters. For example, nematic LCs are characterized using $S_2 \neq 0$. Similarly, the physical properties of surface layers such as monolayers are described using nonzero order parameters S_1, S_2, and S_3. Obviously, nonzero values for the parameters, S_1 and S_3 are specific parameters, are connected to symmetry breaking. In other words, the specific physico-chemical properties of surface layers, for example, monolayers are expressed using nonzero S_1 and S_3. Hence, the generation of SH from surface layers can be discussed in terms of orientational order parameters S_1 and S_3.

23.3
Nonlinear Polarization and Surface Optical Second Harmonic Generation

In the absence of a static electric field, that is, a DC field, the SHG signal originates from a nonlinear dielectric polarization produced by the quantum interaction between the electrons in molecules and the external electric field, that is, laser light Bloembergen, 1965; Shen, 1984. Under the electric dipole approximation, SHG is allowed from the noncentrosymmetric system. On account of symmetry breaking, organic monolayers on metal, film, and water surface possess a noncentrosymmetric structure. Hence, SHG is available for characterizing orientational structure of such monolayers.

Interestingly, SHG is also allowed from a centrosymmetric system if the electric quadrupole effect is prominent. SHG due to the quadrupole effect is a bulk phenomenon and observed in thin films composed of centrosymmetric molecules such as phthalocyanine (Pc) Chollet, Kajzar and Le Moigne, 1990, fullerene (C_{60}) Wang *et al.*, 1992, and other organic molecular films. Fortunately, the resonant conditions are different between the electric dipole mechanism and the electric quardrupole mechanism, and one can distinguish the two mechanisms by appropriately choosing a wavelength of laser used in the SHG experiment.

On the other hand, in the presence of a static electric field, the electron distribution of any centrosymmetric molecule is distorted, and an effective dipole can be induced (DC-field-induced dipole). In this situation, a different type of nonlinear polarization is produced in the centrosymmetric molecular system, and SH can be freshly generated. This is called *electic-field-induced SHG* (*EFISHG*). In organic electronic devices, there are many origins leading to the formation of local static electric field Sze, 1981; Sessler, 1987. Obviously external DC biasing used for the organic device operation is one of the possible origins. A displacement of excess charges at the metal–organic material system, injection of carriers form the metal electrode into the organic device, and so on, are other possible origins. In the following sections, our discussion is focused on SHG due to the electric dipole effect and EFISHG, because these SHG processes are very important for probing surface polarization and related phenomena.

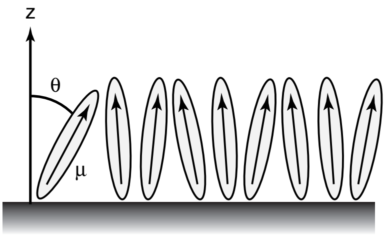

Fig. 23.1 Schematic image of the molecular orientation on a material surface.

23.3.1
SHG as a Tool for Characterizing Surface Structure

The orientational order of organic monolayers comprised of rodlike molecules is specified by using nonzero orientational order parameters, S$_n$ ($n = 1, 2, 3$), defined by the thermodynamic average of the Lagendre polynomials, P$_n$(cos θ) ($n = 1, 2, 3$), of the orientational angle θ of molecules from the normal to the surface (Figure 23.1) Iwamoto and Wu, 2000; Luckhurst and Gray, 1979. Nonlinear dielectric polarization contributing to the SHG is characterized by the second-order nonlinear electronic polarizability $\langle \overset{\leftrightarrow}{\alpha}^{(2)} \rangle$ at an angular frequency ω of the external electric field. This polarization is expressed approximately as

$$\mathbf{P}^{(2)} = \chi^{(2)} : \mathbf{EE} = N_s \langle \overset{\leftrightarrow}{\alpha}^{(2)} \rangle : \mathbf{EE} \quad (23.1)$$

The second-order susceptibility (SOS) $\chi^{(2)} \equiv [\chi_{ijk}]$ of the monolayer is related to the components of the nonlinear molecular electronic polarizability $\alpha_{i',j',k'}$ by $\chi_{ijk} = N_s \langle T_{ijk}^{i'j'k'} \rangle \alpha_{i'j'k'}$, where $T_{ijk}^{i'j'k'} = R_i^{i'} R_j^{j'} R_k^{k'}$ with the usual Euler rotation matrix $R(\phi, \theta, \psi) = [R_i^{i'}]$ describing the coordinate transformation between the molecular system (i', j', k') and the laboratory system (x, y, z) Heinz, 1991. The complete expression of the macroscopic SOS tensor $\chi^{(2)}$ of a monolayer with C_∞-symmetry on a material surface is obtained as a function of the components of the molecular nonlinear electronic polarizability $\alpha_{i',j',k'}$ and the orientational order parameters $S_n \equiv \langle P_n(\cos\theta) \rangle$. With SHG one can deduce $\chi^{(2)}$.

Nonlinear polarization $\mathbf{P}^{(2)} = \mathbf{P}^N$ is a sum of the polarization $\mathbf{P}_{\mathrm{ch}}^N$ associated with the chirality of the monolayer and the polarizations $\mathbf{P}_{\mathrm{ach}}^N$ associated with the nonchirality of the monolayer. The two polarizations in vector form are Iwamoto, Wu and Ou-Yang, 2000

$$\begin{aligned} \mathbf{P}_{\mathrm{ch}}^N = {} & \frac{1}{2} s_{14} [(\mathbf{E} \cdot \mathbf{n})(\mathbf{F} \times \mathbf{n}) + (\mathbf{F} \cdot \mathbf{n}) \\ & \times (\mathbf{E} \times \mathbf{n})] + \frac{1}{2} a_{14} (\mathbf{E} \times \mathbf{F}) \\ & + \frac{1}{2} (a_{36} - a_{14}) \mathbf{n} \cdot (\mathbf{E} \times \mathbf{F}) \mathbf{n} \end{aligned} \quad (23.2)$$

$$\begin{aligned} \mathbf{P}_{\mathrm{ach}}^N = {} & (s_{33} - s_{15} - s_{31})(\mathbf{n} \cdot \mathbf{E})(\mathbf{n} \cdot \mathbf{F}) \mathbf{n} \\ & + s_{31} (\mathbf{E} \cdot \mathbf{F}) \mathbf{n} + \frac{1}{2} s_{15} [(\mathbf{n} \cdot \mathbf{F}) \mathbf{E} \\ & + (\mathbf{n} \cdot \mathbf{E}) \mathbf{F}] + \frac{1}{2} a_{15} (\mathbf{E} \times \mathbf{F}) \times \mathbf{n} \end{aligned} \quad (23.3)$$

with seven independent nonzero elements given as

$$s_{14} = \frac{N_s}{2} S_2 (\sigma_{14} - \sigma_{25}) = \chi_{123} + \chi_{132}$$

$$\begin{aligned}
s_{15} &= \frac{N_s}{5}(S_1 - S_3)(2\sigma_{33} - \sigma_{32} - \sigma_{31}) \\
&\quad + \frac{N_S}{10}(3S_1 + 2S_3)(\sigma_{24} + \sigma_{15}) \\
&= \chi_{131} + \chi_{113} \\
s_{31} &= \frac{N_s}{10}(S_1 - S_3)(2\sigma_{33} - \sigma_{24} - \sigma_{15}) \\
&\quad + \frac{N_S}{10}(4S_1 + S_3)(\sigma_{32} + \sigma_{31}) \\
&= \chi_{311} \\
s_{33} &= \frac{N_s}{5}(S_1 - S_3)(\sigma_{32} + \sigma_{31} + \sigma_{24} \\
&\quad + \sigma_{15}) + \frac{N_s}{5}(3S_1 + 2S_3)\sigma_{33} \\
&= \chi_{333} \\
a_{14} &= \frac{N_s}{3}(\lambda_{14} + \lambda_{25} + \lambda_{36}) \\
&\quad + \frac{N_s}{6}S_2(\lambda_{14} + \lambda_{25} - 2\lambda_{36}) \\
&= \chi_{123} - \chi_{132} \\
a_{15} &= \frac{N_s}{2}S_1(\lambda_{15} - \lambda_{24}) = \chi_{131} - \chi_{113} \\
a_{36} &= \frac{N_s}{3}(\lambda_{14} + \lambda_{25} + \lambda_{36}) \\
&\quad + \frac{N_s}{3}S_2(2\lambda_{36} - \lambda_{14} - \lambda_{25}) \\
&= \chi_{312} - \chi_{321}
\end{aligned} \tag{23.4}$$

where the two 3 × 6 matrices, (σ_{ij}) and (λ_{ij}), are defined by the components of the nonlinear molecular polarizability $\alpha_{i',j',k'}$ in the same way as the conventional contracted notation of (s_{ij}) and (a_{ij}) defined from $\chi^{(2)}$ Shen, 1984; Nye, 1957, that is, $\sigma_{11} = \alpha_{111}$, $\sigma_{14} = \alpha_{123} + \alpha_{132}$, $\lambda_{14} = \alpha_{123} - \alpha_{132}$, and so on, and **E** and **F** are the external electric fields. **n** is unit vector normal to the water surface. In Eqs (23.2) and (23.3), two kinds of external electric fields **E** and **F** are used. In the SHG measurement, the same electric field **E** = **F** from an optical source is used, but in the SFG measurement, and so on, two independent electric field sources **E** ≠ **F** are used. Here, we confine our discussion to the case of SHG, but we can carry similar discussion on SFG, and so on, using Eqs (23.2) and (23.3). In the following analysis, therefore **E** = **F** is assumed.

From a nonlinear polarization point of view, the orientational order parameters S_1 and S_3 are related to the nonlinear polarization associated with the nonchirality of the surface monolayers, whereas S_2 is related to the nonlinear polarization associated with the chirality of the surface layers. In the case of monolayers with $C_{\infty v}$-symmetry, where the constituent molecules are achiral, that is, $s_{14} = a_{14} = a_{36} = 0$, the nonlinear electric polarization in SHG (**E** = **F**) reduces to

$$\begin{aligned}
\mathbf{P}^N &= (s_{33} - s_{31} - s_{15})(\mathbf{n}\cdot\mathbf{E})^2\mathbf{n} \\
&\quad + s_{31}(\mathbf{E}\cdot\mathbf{E})\mathbf{n} + s_{15}(\mathbf{n}\cdot\mathbf{E})\mathbf{E}
\end{aligned} \tag{23.5}$$

The nonlinear dielectric polarization is a function of the order parameters S_1 and S_3 together with the three elements related to the nonchirality, s_{31}, s_{33}, and s_{15}.

Similarly, in case of monolayers with C_∞-symmetry, where the constituent molecules are chiral, that is, $s_{14} \neq a_{14} \neq a_{36} \neq 0$, the nonlinear electric polarization in SHG (**E** = **F**) is given by:

$$\begin{aligned}
\mathbf{P}^N &= s_{14}(\mathbf{E}\cdot\mathbf{n})\cdot(\mathbf{E}\times\mathbf{n}) \\
&\quad + (s_{33} - s_{31} - s_{15})(\mathbf{n}\cdot\mathbf{E})^2\mathbf{n} \\
&\quad + s_{31}(\mathbf{E}\cdot\mathbf{E})\mathbf{n} + s_{15}(\mathbf{n}\cdot\mathbf{E})\mathbf{E}
\end{aligned} \tag{23.6}$$

The first term on the right-hand side of Eq. (23.6) as a function of s_{14} with

S_2 (see Eq. (23.4)) represents the chiral effect. As mentioned earlier, the quantum interaction between the electrons in molecules and the external electric field makes the main contribution to SHG, and thus the nonlinear dielectric polarization given by Eqs (23.2) and (23.3) becomes the main contribution to the SHG. Equations (23.5) and (23.6) suggest that one can determine the orientational order parameters of S_1, S_2, and S_3 by means of SHG caused by the electric dipole effect.

23.3.2
EFISHG as a Tool for Probing Excess Surface Charges

The nonlinear polarization for the SHG in the medium is expressed not only as Eq. (23.1) under the electric dipole approximation but also in well-known tensor form as Shen, 1984

$$P_i = \chi^D_{ijk} E_j(\omega) E_k(\omega) \tag{23.7}$$

where χ^D_{ijk} is the second-order nonlinear susceptibility due to the electric dipole mechanism, and E_j and E_k are the electric fields of fundamental laser light. The effective polarization due to the electric quadrupole also contributes to the second-order nonlinear polarization, and it is expressed as

$$P_i = \chi^Q_{ijkl} \partial_j E_k(\omega) E_l(\omega) \tag{23.8}$$

where χ^Q_{ijkl} is the second-order nonlinear susceptibility due to the electric quadrupole mechanism.

On the one hand, second-order nonlinear polarization is activated by the external static field in case of the DC EFISHG. Since three electric fields $E_j(0)$, $E_k(\omega)$, and $E_l(\omega)$, are concerned with the generation of the nonlinear polarization, the nonlinear optical susceptibility becomes fourth-order rank tensor that does not vanish even in the centrosymmetric system. Thus, the effective polarization is expressed as

$$P_i = \chi^{\mathrm{DC}}_{ijkl} E_j(0) E_k(\omega) E_l(\omega) \tag{23.9}$$

where $E_j(0)$ is the external static electric field induced by the local electric field, and $\chi^{\mathrm{DC}}_{ijkl}$ is the third-order nonlinear susceptibility due to the DC-induced mechanism and $\chi^{\mathrm{DC}}_{ijkl} E_j(0)$ corresponds to the effective dipole induced. Note that although this contribution is the third-order nonlinear optical process, double frequency of the fundamental light is generated because one of the related field is static. As mentioned earlier, there are many possible origins leading to the generation of nonzero local electric field $\mathrm{E}_j(0) \neq 0$. Among them are external electric field, injected carriers, trapped charges, and so on. Hence, we can probe these local electric fields $\mathrm{E}_j(0)$ by means of EFISHG.

23.3.3
Spectroscopic Consideration of the SHG

SHG originates from the quantum interaction between the electrons in molecules and the external electric field. In this section, we briefly summerize the SHGs from the viewpoint of energetics based on the quantum theory. As mentioned in the earlier sections, we should take into account the following three contributions to the SHG:

- electric dipole mechanism (χ_D);
- electric quadrupole mechanism (χ_Q); and
- induced electric dipole mechanism (χ_{DC})

and the nonlinear optical susceptibilities originated from these contributions show the different dependence on the wavelength of each related electric field, owing to the difference in the quantum interaction between the electrons in the molecules and the electric field. Thus, we can distinguish each mechanisms from a view point of spectroscopy. There are many ways to evaluate the frequency-dependent nonlinear susceptibilities. According to the quantum mechanical perturbation theory, the nonlinear susceptibilities for the SHG can be calculated as the second-order contribution to the induced dipole moment. Some of the molecular orbital (MO) calculation programs also enable us to estimate the frequency-dependent nonlinear susceptibilities. First, we discuss the resonant condition for the SHG schematically.

Schematic images for the resonance conditions are shown in Figure 23.2. In this figure, state $|g\rangle$ represents a ground state and $|n\rangle$, $|m\rangle$, and $|p\rangle$ represent the virtual excited states. Selection rules are employed to discuss the SHG, that is, the transitions between states of the same parity are forbidden for the electric dipole transition, whereas transitions between states of the same parity are allowed for the electric quadrupole transition. Considering these diagrams and the selection rules, we can estimate the resonant conditions for the SH frequency, 2ω. Clearly, for the electric dipole mechanism (Figure 23.2(a)), the lack of the centrosymmetry is required to radiate the SH wave, and resonance enhancement occurs only when the SH photon energy is coincident with the allowed excited state. On the other hand, resonance enhancement occurs only when the SH photon energy is coincident with the forbidden excited state for the electric quadrupole mechanism (Figure 23.2(b)). The case of the induced electric dipole mechanism is slightly different. This process is activated by the external field, as mentioned above. As shown in Figure 23.2(c), state $|n\rangle$ overlies $|p\rangle$ state. This indicates that the resonance enhancement occurs when the SH photon energy is coincident with both the allowed and forbidden excited states for this mechanism. Taking into account the resonant conditions discussed above, we can discuss the origin of the SHG from organic film by the spectroscopic observation. In more detail, χ_D, χ_Q and χ_{DC} are described as

$$\chi_{ijk}^{D} \propto \sum_{m,n} \left(\frac{\langle g|\hat{\mu}_i|n\rangle\langle n|\hat{\mu}_j|m\rangle\langle m|\hat{\mu}_k|g\rangle}{\left(\omega_{ng} - 2\omega\right)\left(\omega_{mg} - \omega\right)} \right.$$

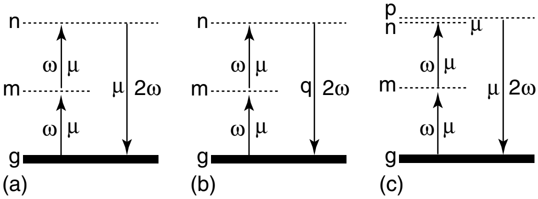

Fig. 23.2 Transition diagrams for the SH process: (a) electric dipole, (b) electric quadrupole, and (c) induced electric dipole.

$$+\frac{\langle g|\hat{\mu}_j|n\rangle\langle n|\hat{\mu}_i|m\rangle\langle m|\hat{\mu}_k|g\rangle}{\left(\omega_{ng}+\omega\right)\left(\omega_{mg}-\omega\right)}$$

$$+\frac{\langle g|\hat{\mu}_k|n\rangle\langle n|\hat{\mu}_j|m\rangle\langle m|\hat{\mu}_i|g\rangle}{\left(\omega_{ng}+\omega\right)\left(\omega_{mg}+2\omega\right)}\Bigg) \qquad (23.10)$$

$$\chi^{Q}_{ijkl} \propto \sum_{m,n}\Bigg(\frac{\langle g|\hat{q}_{ij}|n\rangle\langle n|\hat{\mu}_k|m\rangle\langle m|\hat{\mu}_l|g\rangle}{\left(\omega_{ng}-2\omega\right)\left(\omega_{mg}-\omega\right)}$$

$$+\frac{\langle g|\hat{\mu}_k|n\rangle\langle n|\hat{q}_{ij}|m\rangle\langle m|\hat{\mu}_l|g\rangle}{\left(\omega_{ng}+\omega\right)\left(\omega_{mg}-\omega\right)}$$

$$+\frac{\langle g|\hat{\mu}_l|n\rangle\langle n|\hat{\mu}_k|m\rangle\langle m|\hat{q}_{ij}|g\rangle}{\left(\omega_{ng}+\omega\right)\left(\omega_{mg}+2\omega\right)}\Bigg) \qquad (23.11)$$

and

$$\chi^{\mathrm{DC}}_{ijkl} \propto$$

$$\sum_{m,n,o}\Bigg(\frac{\langle g|\hat{\mu}_i|p\rangle\langle p|\hat{\mu}_j|n\rangle\langle n|\hat{\mu}_k|m\rangle\langle m|\hat{\mu}_l|g\rangle}{\left(\omega_{pg}-2\omega\right)\left(\omega_{ng}-2\omega\right)\left(\omega_{mg}-\omega\right)}+\frac{\langle g|\hat{\mu}_j|p\rangle\langle p|\hat{\mu}_i|n\rangle\langle n|\hat{\mu}_k|m\rangle\langle m|\hat{\mu}_l|g\rangle}{\omega_{pg}\left(\omega_{ng}-2\omega\right)\left(\omega_{mg}-\omega\right)}$$

$$+\frac{\langle g|\hat{\mu}_j|p\rangle\langle p|\hat{\mu}_k|n\rangle\langle n|\hat{\mu}_i|m\rangle\langle m|\hat{\mu}_l|g\rangle}{\omega_{pg}\left(\omega_{ng}+\omega\right)\left(\omega_{mg}-\omega\right)}+\frac{\langle g|\hat{\mu}_j|p\rangle\langle p|\hat{\mu}_k|n\rangle\langle n|\hat{\mu}_l|m\rangle\langle m|\hat{\mu}_i|g\rangle}{\omega_{pg}\left(\omega_{ng}+\omega\right)\left(\omega_{mg}+2\omega\right)}\Bigg) \qquad (23.12)$$

where $\hat{\mu}_i$ and $\hat{q}_{ij}$ are the electric dipole and the electric quadrupole transition moment operator and are expressed as $\hat{\mu}_i = -e\hat{r}_i$ and $\hat{q}_{ij} = -\frac{1}{6}e(3\hat{r}_i\hat{r}_j - \mathbf{r}^2\delta_{ij})$, respectively. $|g\rangle$ represents a wave function of the ground state and $|m\rangle$ and $|n\rangle$ are those of the excited state. The notation ω_{mg} means the frequency difference between $|m\rangle$ state and $|g\rangle$ state, $\omega_m - \omega_g$.

However, we do not need to go into the details of χ_D, χ_Q, and χ_{DC}, when we use the SHGs for probing the orientational order of surface molecules and for probing the local electric field.

Equations (23.10)–(23.12) suggest that it is important to know the origins of SHG enhancement in terms of the resonant frequency.

23.3.4
Sum-Frequency Generation

In this section, SFG is described. SFG also becomes a powerful tool for investigating the surface and interface phenomena of materials, especially on the molecular level. For the SFG process, three optical waves with different frequencies are interacting. There is an energy conservation between two input waves (ω_1 and ω_2) and output wave (ω_3) as $\omega_1 + \omega_2 \to \omega_3$. As mentioned, both SHG and SFG are second-order nonlinear optical processes, and in other words, SFG is a generalization of SHG (ω_1 and ω_2 are degenerate for the SHG process). Accordingly, the SFG output vanishes from the materials with inversion symmetry under the electric dipole approximation as well as the SHG process. We can realize the surface selective vibrational spectroscopy measurement by using SFG, letting the input wave with a frequency ω_1 be visible and the wave with a frequency ω_2 be infrared light.

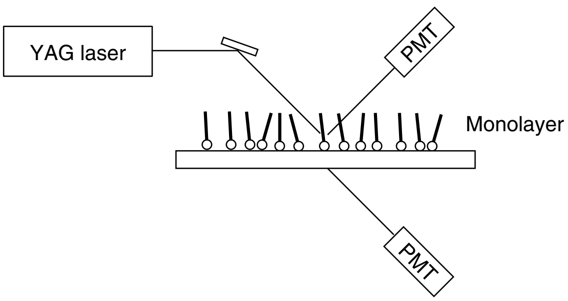

Fig. 23.3 Schematics of experimental setup for SHG measurement system is also attached. The chemical structure of 8CB.

23.4
Measurement Details of SHG and EFISHG

23.4.1
Determination of Surface Structure and Orientational Order Parameters

23.4.1.1 Fundamentals

SH light is generated from the monolayer by laser irradiation. The input light consists of the *s*- and the *p*-polarized waves and is expressed as

$$\mathbf{E}_{\text{in}} = S_\omega \mathbf{s}_{\text{in}} + P_\omega \mathbf{p}_{\text{in}} \tag{23.13}$$

where $\mathbf{s}_{\text{in}}$ and $\mathbf{p}_{\text{in}}$ are unit vectors for the *s*- and the *p*-polarized direction of the waves, and S_ω and P_ω are the amplitude of the *s*- and the *p*-polarized waves, respectively. Substituting $\mathbf{E}_{\text{in}}$ into Eqs (23.5) and (23.6), $\mathbf{P}^N$ generated in surface monolayers is obtained. The output light intensity $I_{2\omega}$ is proportional to $\mathbf{e}_{\text{out}}(2\omega) \cdot \mathbf{P}^N$, where $\mathbf{e}_{\text{out}}$ is unit vector for the output light direction of the wave. Since $\mathbf{e}_{\text{out}}(2\omega) \cdot \mathbf{P}^N$ is a function of S_1, S_2, and S_3, these orientational order parameters of surface monolayers can be determined with the enhanced SHG by the electric dipole effect Zhu, Suhr and Shen, 1987.

23.4.1.2 Experimental Configuration of SHG Measurement

Figure 23.3 shows a schematic diagram of the SHG measuring system for probing nonlinear polarization of surface layers. The SHG experiments can be carried out with the experimental setup illustrated. Briefly, the experimental setup consists of an optical measurement arrangement with a Q-switched Nd : YAG laser (wavelength 0.532 μm, pulse duration <7 nanoseconds, fundamental pulse rate $\leq$ 15 Hz) for the SHG measurement. The laser light is irradiated onto the surface layer with an energy of about 6 mJ at a pulse rate of 2 Hz. The size of the laser spot is about 56.0 mm^2.

23.4.1.3 Experimental Configuration of SFG Measurement

We can observe the SFG output of visible light, and a typical photomultiplier tube (PMT) can be used as a detector. Figure 23.4 represents the typical setup for the SFG measurement. Owing to the photon momentum conservation, the direction of SFG output is not

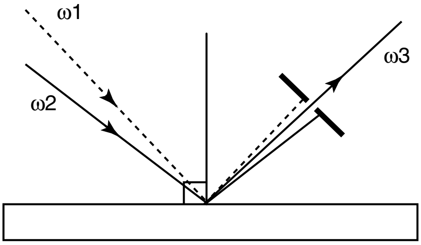

Fig. 23.4 Paths of light rays in SFG measurement.

coincident with those either of reflected fundamental waves (see Figure 23.4).

Experimentally, surface vibrational spectroscopy was first introduced by Zhu, Suhr and Shen 1987. They successful recorded a vibrational spectrum of a monolayer of molecules on a substrate by SFG. They chose second harmonics of YAG laser as a visible input and coumarin dye so that the resonance enhancement of the SFG signal occurred. They also mentioned the possibility to detect the transient surface phenomena because pulsed laser probing in SFG enables us to monitor the transient species appearing on a surface. As mentioned, SHG can also detect the orientation of molecules on a surface. Since the origin of SHG process involves electronic transitions in the molecule, the orientation of molecules directly reflects the orientation of the transition moments. In contrast, SFG can detect the orientation of the functional group of the molecule. In this sense, detailed information of the surface can be extracted from the SFG results.

23.4.2
Probing of the SHG Intensity Profile as a Convolution Beam Pattern

23.4.2.1 **Fundamentals**

For EFISHG, the SHG intensity is proportional to the square of local static electric field as

$$I(2\omega) \propto \left| \chi^{(3)}(-2\omega; 0, \omega, \omega) \times E(0)E(\omega)E(\omega) \right|^2 \quad (23.14)$$

where $\chi^{(3)}(-2\omega; 0, \omega, \omega)$ represents a third-order nonlinear optical (NLO) susceptibility for the EFISHG process, and $E(0)$ and $E(\omega)$ represent the static electric field and electric field of light, respectively. External electric fields, trapped charges, and injected carriers are origins of the static electric field, $E(0)$. Hence, the electric field distribution in materials as well as in organic devices can be obtained at various experimental conditions by the EFISHG measurement. In more detail, SHG intensity profile can be considered as a convolution of the beam pattern of the fundamental laser and the actual electric field distribution formed in organic films as Tojima, Manaka and Iwamoto, 2001

$$I^{2\omega}(x) \propto \left| \int_{-\infty}^{\infty} E(\xi) I^{\omega}(x-\xi) d\xi \right|^2 \quad (23.15)$$

$I^{2\omega}(x)$ represents the SHG intensity at position x, and $E(\xi)$ and $I^{\omega}(\xi)$ represent the electric field distribution and the intensity profile of the fundamental laser, respectively. If the laser beam

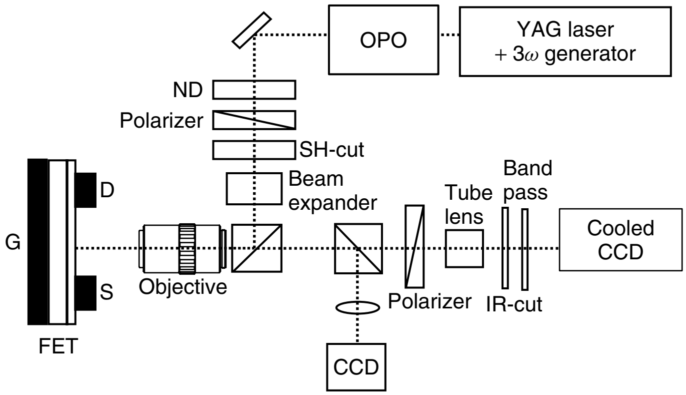

Fig. 23.5 Optical setup for the EFISHG measurement of OFET devices.

profile is approximated by δ-function as $I^{\omega}(x) \equiv \delta(x)$, $\sqrt{I^{2\omega}(x)}$ directly gives the local electric field $E(x)$. However, to obtain the accurate electric field distribution from the SHG, intensity profile requires a deconvolution process taking into consideration the beam profile of the fundamental laser, $I^{\omega}(x)$. Such deconvolution is, in general, a laborious task, because a beam profile and the SHG intensity profile are not expressed by simple mathematical functions, and the evaluated electric field from a scanning measurement sometimes loses accuracy, for example, spatial resolution. We can employ the deconvolution process for the determination of electric field distribution. On the other hand, an SHG imaging technique for visualizing the distribution of the electric field in organic materials can overcome these problems Manaka *et al.*, 2006. The evaluation of the electric field distribution from SHG images does not require the complicated deconvolution process, and the spatial resolution is significantly improved. Moreover, omission of the scanning process results in the reduction of the measurement time.

23.4.2.2 **Experimental Configuration of EFISHG Measurement from OFET Structure**

A detailed configuration about the EFISHG measurement is described in Manaka *et al.*, 2006. Figure 23.5 shows a schematic diagram of the EFISHG measuring system. The light source for the SHG measurement is an optical parametric oscillator (OPO: Continuum Surelite OPO), pumped by a third-harmonic light of Q-switched Nd–YAG laser (Continuum: SureliteII-10), a fundamental wavelength of 1120 or 1320 nm is chosen. Fundamental light from the OPO passes through a prism polarizer, long-pass filters, and a beam expander. Then it is focused on the sample with normal incidence, using a long working distance objective lens (Mitutoyo: M Plan Apo SL20 × ,NA = 0.28, WD = 20.5 mm). SH light generated from the sample is filtered by a fundamental-cut filter and an interference filter to remove fundamental and other unnecessary light. Finally, SH light is detected by a cooled charge coupled device (CCD) camera (Andor technology: DU420-BV). In this configuration, the polarization

direction of the light is chosen in the direction parallel to the sample surface.

23.5
Results of SHG and EFISHG

23.5.1
Determination of Surface Structure and Orientational Order Parameters

In a manner as described in Section 23.3.1, we can carry out SHG experiment for probing orientational order of surface layers. Figure 23.6 shows an example of the determination of the order parameters S_1 and S_3 for 4-*n*-octyl-4′-cyanobiphenyl (8CB) monolayers with $C_{\infty v}$-symmetry on water surface. In region 1, S_1 and S_3 of SHG are very small, although fluctuations coming from the formation of domains are observed. In region 2, S_1 and S_3 increase gradually and show the maximum with decrease in the molecular area. In region 3, they are nearly constant, about 0.5. In contrast, S_1 determined by electrical Maxwell-displacement current (MDC) measurement is also plotted. S_1 is nearly zero in region 1 and increases monotonically in region 2. S_1 is about 0.5 in region 3. These results suggest that 8CB molecules lying on a water surface in large molecular area progressively stand up with a decrease in the molecular area and with an average tilting angle of about 60° in region 2. As mentioned earlier, surface polarization phenomena can be detected and the orientational orders of the surface layers can be well explored by the SHG caused by the electric dipole effect.

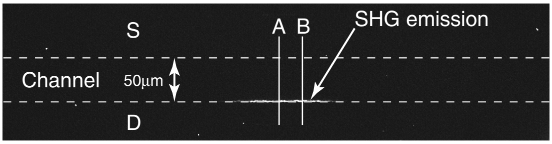

Fig. 23.7 SHG image from the channel of pentacene FET under the application of negative pulse. Channel region lies between two gold electrodes, and edges of the electrode are indicated by dashed lines. SHG emission was observed at the edge of the drain electrode.

23.5.2
Probing of Electric Field $E(0)$ by EFISHG Measurement

As mentioned in Section 23.3.2, the SHG intensity profile obtained on the basis of a scanning measurement does not display an actual spread of SHG emission from the material surface. Direct observations of the SHG image can show a more realistic distribution of the SHG emission within the limits of the system resolution. Figure 23.7 shows the SHG image from the channel of pentacene field effect transistor (FET) under the application of negative pulse. As shown in this figure, strong SHG emission is observed at an edge of drain electrode. High electric fields between the drain and gate electrodes produce a large in-plane component of the electric field, which activates the SHG at the drain edge. It is noteworthy that the width of the SHG emission in the channel clearly decreases compared with a distribution obtained on the basis of a scanning measurement.

Figure 23.8 shows the line scan of the SHG intensity profile across the channel (represented as open squares and filled diamonds) and the in-plane component of the in-plane electric field

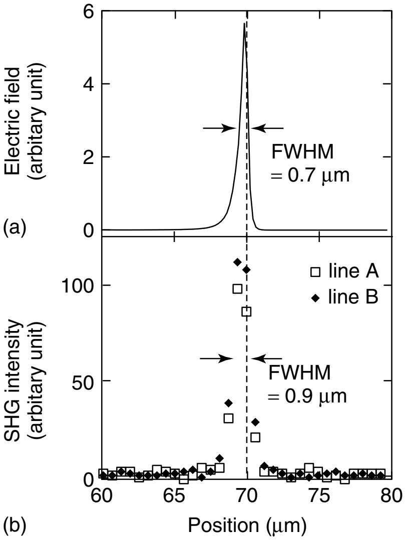

Fig. 23.8 (a) The figure represents the in-plane component of the in-plane electric field distribution in pentacene layer calculated based on a finite element method. (b) The figure shows the line scan of the SHG intensity profile across the channel. Open squares and filled diamonds, respectively, represent SHG intensity profile at line scan A and B as shown in Figure 23.7.

distribution (solid line) in the pentacene layer. Open squares and filled diamonds, respectively, represent the SHG intensity profile at line scan *A* and *B* (see Figure 23.7) as shown in Figure 23.8. The edge of the electrode is located at a position of 70 μm in these figures. It is found that the SHG intensity profile is quite sharp. The sharpness of emission is quantitatively estimated using full width at half maximum (FWHM) values of the profile. FWHM values of SHG profile and the electric field distribution are evaluated as 0.9 and 0.7 μm, respectively. Note that FWHM values of the SHG profile obtained based on the scanning measurement depended on the magnification of the objective lens and have the value of approximately 15 μm for 20 × objective.

For the electric field calculation when there are no excess charges in the device, only the electrode configuration and potential of the electrode are taken into account. In such a case, a Laplacian electric field is formed in the device. A Laplacian field is the electric field caused by the potentials of electrodes in the absence of any charges in the devices between the electrodes. Under negative bias, carrier injection from the electrode into pentacene is prohibited because the injection barrier for electrons at the pentacene/Au interface is quite high, that is, energy difference between the lowest unoccupied molecular orbital (LUMO) of pentacene and the work function of Au electrode is evaluated as 2.7 eV. Thus, the strong electric field around the edge of the electrode is maintained during bias application, and the SHG emission is concentrated around the edge of the drain electrode as shown in Figure 23.7. In other words, the sharp emission of the SHG at the edge of the electrode indicates that the SHG imaging technique successfully visualizes the electric field in the device with a spatial resolution of approximately 1 μm. As mentioned above, the electric field generated by the Laplacian electric field can be detected as the EFISHG, and the distribution of the electric field can be explored using the profile of EFISHG enhanced. Similarly, the electric field distribution caused by injected carriers and trapped charges can be evaluated by the EFISHG Zhu, Suhr and Shen, 1987. It is instructive to note that the migration of the peaks of electric field caused by injected carries is visualized by means of TRM-SHG measurement Manaka *et al.*, 2007a. Further, OFET operation has been successfully probed by SFG, where conformational change of the molecular structure, due to dopings of the molecules by carrier injection from electrodes, is probed Manaka *et al.*, 2007b.

26.1
Principles of Vibrational Spectroscopy

26.1.1
Introduction

Infrared spectroscopy is routinely used in analytical laboratories for the identification of materials, molecules, and functional groups through their characteristic absorption patterns in the mid-infrared (4000–400 cm^{-1}) region of the electromagnetic spectrum. In its original conception, analytical infrared spectroscopy was based upon simple dispersive instrumentation measuring the transmitted proportion of light as a function of wavelength through a sample. Over the last 30 years, the development of interferometric methods for the measurement of frequency-domain spectra, sophisticated reflection-based sampling methods applicable to non-transparent materials, and computer-based processing methods has transformed the field into a widely applicable, quantitative method for materials analysis. In this chapter, the basic principles of infrared spectroscopy are outlined, along with a brief account of the measurement and interpretation of infrared spectra. In addition, some topical examples of the use of modern infrared spectroscopy in physics, chemistry, biology, and atmospheric science are also presented.

26.1.2
Classical and Quantum-Mechanical Description of Infrared Vibrational Excitation in Diatomic Molecules

In any form of absorption spectroscopy, the energy absorbed in a *transition* between energy levels is measured. In the mid-infrared region, these transitions correspond to changes in vibrational quantum number. Before treating the system in a quantum-mechanical manner, however, a simpler classical treatment is instructive in order to give a phenomenological perspective. The most basic classical approach relating vibrational transitions to visualizable molecular parameters treats a vibrating diatomic molecule as two masses m_1 and m_2 (in kilograms) connected by a flexible bond with a force constant k (newton per meter) using Hookes' Law, as shown in Figure 26.1.

When the masses are at equilibrium, $r = r_{\text{eqm}}$ and there are no forces acting. However, when the bond is elongated

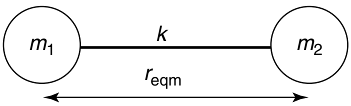

Fig. 26.1 Schematic of the basis of the simple harmonic oscillator model for a heteronuclear diatomic model. The terms are defined in the text.

(or compressed), a restoring force acts to pull (or push) the particles:

$$F(r) = -k(r - r_{\text{eqm}}) \qquad (26.1)$$

Thus, the masses oscillate around the equilibrium distance. It can be shown that the oscillation frequency is given as

$$\nu = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}} \quad (\text{s}^{-1}) \qquad (26.2)$$

where k is the force constant as defined above and μ is the reduced mass (in kilograms):

$$\frac{1}{\mu} = \frac{1}{m_1} + \frac{1}{m_2} \quad \text{or} \quad \mu = \frac{m_1 m_2}{m_1 + m_2} \qquad (26.3)$$

Replacing the masses and force constants with representative atomic values, the oscillation frequencies obtained are typically between 1.2×10^{13} and 1.2×10^{14} Hz.

The nature of the interaction between the electric field of the infrared radiation and the atoms of the molecule can best be envisaged by considering a heteronuclear diatomic molecule, where the atoms at either end of the bond have different electronegativities. This polarization results in a dipole moment, the magnitude of which oscillates with the changing bond length during vibrational motion. The electric field E associated with electromagnetic radiation also oscillates in amplitude with time like a dipole with frequency ν (s^{-1}):

$$E(t) = E_0 \cos(2\pi\nu t) \qquad (26.4)$$

When the frequency of oscillation of the molecule is resonant with the frequency of the infrared radiation, absorption of energy by the molecule can occur. In practice, the requirement for a permanent dipole moment exists only for diatomic molecules and for more complicated polyatomic molecules; several atoms (connected by a number of bonds) may move at once, resulting in a changing (*dynamic*) dipole moment during the course of the vibration even if a static dipole moment does not exist. Figure 26.2 illustrates this for the antisymmetric stretching mode of CO_2. This phenomenon is often expressed as an empirical selection rule for the infrared activity of a given vibration, that is, during the course of a particular vibration the molecular dipole moment must change.

From a quantum-mechanical perspective, the problem of quantifying vibrational absorption activity and of calculating energy levels and intensities relies upon the identification of appropriate operators and wavefunctions to describe

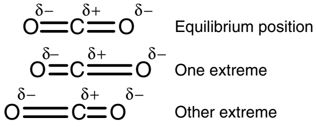

Fig. 26.2 Schematic of the atomic displacements contributing to the antisymmetric stretching mode of CO_2.

the system. Naturally, each energy level of the quantized vibrational motion will be described by a wavefunction, which must be an eigenfunction equation of the Schrödinger equation:

$$\hat{H}\Psi = E\Psi \tag{26.5}$$

The Hamiltonian has both kinetic and potential energy components describing the vibrational motion. A simple treatment that serves to extend the classical treatment into the quantum world treats the potential energy as deriving from Hookes' law, Eq. (26.1). The potential energy operator takes the following form:

$$\hat{V} = \frac{1}{2}kx^2 \tag{26.6}$$

where $x = r - r_{\text{eqm}}$. The kinetic energy operator can be taken directly from the known result:

$$\hat{T} = -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} \tag{26.7}$$

Combining these equations together and using the fact that $m = \mu$ for diatomics, we obtain

$$\hat{H}\Psi = -\frac{\hbar^2}{2\mu}\frac{\partial^2\Psi}{\partial x^2} + \frac{1}{2}kx^2\Psi \tag{26.8}$$

This treatment is usually referred to as the *simple harmonic oscillator,* and suitable wavefunctions take the following form:

$$\Psi_{\text{v}} = \sqrt{\left(\frac{1}{2^{\text{v}}v!\sqrt{\pi}}\right)} \times H_{\text{v}}(y) \times \exp\left(\frac{-y^2}{2}\right) \tag{26.9}$$

where v is the *vibrational quantum number* and $H_v(y)$ are called *Hermite polynomials,*

v	$H_v(y)$
0	1
1	$2y$
2	$4y^2 - 2$
3	$8y^3 - 14y$

where y is given as

$$y = \left(\frac{4\pi^2\nu\mu}{h}\right)^{1/2} \times (r - r_{\text{eqm}}) \tag{26.10}$$

Transitions between these energy levels then correspond to vibrational absorption. Solving Eq. (26.8) with these eigenfunctions results in the well-known value for the energy of a given level v:

$$E = h\nu\left(v + \frac{1}{2}\right) \tag{26.11}$$

where ν is the classical frequency given in Eq. (26.2). Also note that these wavefunctions are normalized and orthogonal. Several interesting quantum-mechanical phenomena appear from this treatment. First, the probability of finding a particle at a position x is given by $|\Psi_v(x)|^2$, suggesting that in the ground state ($v = 0$), the oscillator spends most of its time at $x = 0$ (i.e., at the center), directly at odds with classical theory. Second, this also points to the existence of zero-point energy since the lowest state of the oscillator has energy $1/2h\nu$.

The quantum-mechanical treatment gives direct access to the magnitude of the spacing between the energy levels and also the selection rules, since the vibrational transition probability can be derived directly from the wavefunctions. The gross selection rule for the classical treatment given earlier still applies: the electric dipole moment must change during the course of a vibration. This is reinterpreted quantum mechanically through the values of the *transition dipole moment* μ_{fi} on going from an initial state Ψ_i to final state Ψ_f, that is, for an allowed transition, $\mu_{fi} \neq 0$. Clearly,

$$\mu_{fi} = \int_{-\infty}^{+\infty} \Psi_f^* \hat{\mu}_i . d\tau = \langle f|\hat{\mu}|i\rangle \quad (26.12)$$

where the electric dipole moment operator $\hat{\mu}$ has the form

$$\hat{\mu} = \sum_j \mathrm{q}_j \mathbf{r}_j \quad (26.13)$$

where q_j is the charge on the jth particle and $\mathbf{r}_j$ is its position vector with respect to the center of mass of the molecule. Evaluation of these parameters for the wavefunctions of the simple harmonic oscillator leads to the selection rule $\Delta v = \pm 1$. In real molecules, the vibrational potential $V(x)$ is not accurately described by a simple harmonic oscillator: the real potential is anharmonic, resembling a *Morse potential*. The energy levels of the anharmonic oscillator are given by

$$E_\mathrm{v} = h\nu\left(\mathrm{v} + \frac{1}{2}\right) - x_e\left(\mathrm{v} + \frac{1}{2}\right)^2 \quad (26.14)$$

where x_e is called the *anharmonicity constant*. Note that the energy levels become more closely spaced as v increases. This allows transitions across quantum numbers and in reality the selection rule is found to be $\Delta v = \pm 1, \pm 2, \pm 3$, and so on. The first of these transitions is referred to as the *fundamental*, with the higher values being the *harmonics* or *overtones*. Furthermore, the reduction in spacing between the energy levels in the anharmonic oscillator leads to the appearance of the harmonics at a slightly lower frequency than twice that of the fundamental. Nothing in the foregoing treatment forbids excitation from energy levels above the ground state, giving rise to what are know as *hot bands*. The name derives from the fact that the populations of the higher vibrational states $N(v)$ follow the Boltzmann distribution:

$$N(\mathrm{v}) = N_0 \exp\left(-\frac{\mathrm{v}h\nu}{kT}\right) \quad (26.15)$$

where N_0 is the ground state population and T is the temperature (kelvin). Given the typical energy spacing of vibrational levels, the population of the first vibrationally excited state is small at room temperature for all but the lowest frequency vibrations and significant populations are only achieved in hot samples. Again, the reduction in spacing between the energy levels in the anharmonic oscillator leads to the appearance of the hot band at a slightly lower frequency that the fundamental.

The intensity I of absorption upon transition from one energy level to another is proportional to the square of the transition dipole moment:

$$I \propto (\mu_\mathrm{fi})^2 \quad (26.16)$$

In infrared transitions, this value depends upon both the amplitude of the vibration (since large excursions give rise to large changes in the relative positions of the atoms) and the relative polarization of the atom(s) at either end of the chemical bond. For example, as will be seen later, vibrations involving oxygen atoms tend to be intense because of the electronegativity of oxygen, and many vibrations involving hydrogen atoms tend to be intense because small, light atoms often experience large displacements. For further details, see Atkins and de Paula (2009) and Hollas (1992).

26.1.3
Group Frequencies and Symmetry in Infrared Vibrational Spectroscopy

In a simple diatomic molecule, vibration involves only the motion of two atoms. Any movement of one atom affects the atom, and since the center of mass must be conserved only one vibration can occur. This is not the case for polyatomic molecules, for which several combinations of atomic displacement are possible. These combinations are not random, since there are constraints in the retention of a fixed center of mass. For a free atom, there are three degrees of freedom, represented by translation in the x, y, and z directions. For two atoms connected together (taking the z axis as the direction between the two atom centers), a total of six degrees of freedom must therefore exist: three translations of the whole molecule (along x, y, and z axes), two rotations (around x and y axes), and one vibration (along the z axis). By extension of this argument, it can easily be seen that for a polyatomic molecule with N component atoms there must be $3N$ degrees of freedom, from which there must be three translations of the whole molecule (along x, y, and z axes) and three rotations (around the x, y, and z axes). This leaves $3N - 6$ degrees of freedom, which must therefore be accounted for by a series of (different) vibrational motions. It should also be noted, however, that if the molecule is linear, there can only be two rotations; hence, there will be $3N - 5$ vibrations in this case.

Each vibration consists of a number of atomic displacements, since it is impossible for only one bond to stretch without affecting all the other atoms and the center of mass of the molecule must remain stationary (otherwise the displacements lead to translational motion or rotation). This is illustrated for H_2O in Figure 26.3. Since there are three atoms in water, there are three vibrational combinations. The simplest motion involves a displacement of each of the H atoms simultaneously and in phase along their respective O—H bonds. To compensate for the motion of the H atoms, it is necessary for the O atom to move in the opposite direction. To retain the center of mass, the vector distance/displacement products must sum to zero; hence, the O atom will move much less than the H atoms for this to occur. This vibration is referred to as the *symmetric stretch*, for reasons that are discussed later. The second identifiable vibrational combination again involves simultaneous displacement of the H atoms along the O—H bond, but this time out of phase. To compensate for this overall motion of the H atoms to the right, the O atom must move proportionally to the left. This vibration is the *antisymmetric stretch*. The remaining vibration involves a different kind of motion: *bending*. In this case, the O atom must move proportionally upward to counteract the motion of the H atoms.

A unique combination of atomic displacements can be found for each vibrational degree of freedom of any

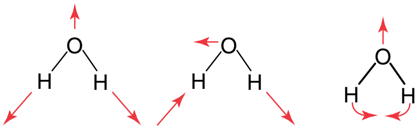

Fig. 26.3 Atomic displacements for the three vibrational modes of H_2O. Note that any allowed combination of displacements must retain the center of mass.

molecule. Each unique combination is referred to as a *normal mode*. As is shown later, some combinations may result in displacements that only differ in the directions in which they occur (e.g., in the x, y plane or the x, z plane) but which occur at the same frequency: such modes are described as *degenerate*. For example, there are three identifiable components of the antisymmetric stretching modes of methane (CH_4), polarized along the x, y, and z axes: all these have the same frequency and are therefore triply degenerate.

In general, for a given normal mode in polyatomic molecules, the individual combination of atomic displacements falls into one of two broad categories: those that are mainly localized on a small subset of atoms and those that involve more complex coupled motion of a significant proportion of the atoms. The former are often readily identifiable with various functional groups of the molecule, the so-called *functional group modes*. A particularly useful example is the stretching of the carbonyl ($>C{=}O$) bond. In many molecules, the vibration of this group is largely decoupled from the rest of the molecule and the mode, therefore, absorbs at roughly the same frequency in a wide range of molecule types. However, functional groups with similar absorption frequencies can couple, a clear example being the functional group modes related to the various components of a secondary amide (containing the $-CO-NH-$functionality). In this case, the carbonyl frequency is close to that of the bending vibration of the NH, and hence strong coupling occurs to give the characteristic *amide I* and *amide II* functional group modes. The former is predominantly, but not exclusively, related to the carbonyl and the latter is related to the NH bending mode. Together, the two bands form a uniquely identifiable motif that strongly features in the infrared spectra of biological materials.

At the other end of the scale, there are normal modes that involve the simultaneous displacement of many atoms within a given molecule. Often, it is very difficult to uniquely assign these modes. However, the combined overlapping collection of these normal modes is a unique characteristic for a given molecule and is responsible for its "fingerprint." Spectra of polyatomic molecules are, therefore, comprised of a complex, unassignable fingerprint spectrum overlaid with more readily identifiable functional group modes.

For simpler polyatomic molecules, the collective displacements of the individual atoms can be described by considering the symmetry properties of the molecule. This leads to a simpler way of determining the vibrational activity of a given normal mode. The first step in this process is the determination of the symmetry properties of the molecule, following the principles of group theory, described in detail elsewhere. This basically involves identifying the collection of symmetry operations (rotations, reflections, improper rotations, centers of inversion, etc.), which can be performed upon the molecule, from which the point group can be determined. For a detailed description of the method, see Vincent (2001).

Once the point group of the molecule in question has been determined, the symmetries of the combinations of atomic displacements for each normal mode can be derived. Three Cartesian displacement vectors are placed on each atom (one for each x, y, and z

component). The effect of the symmetry operations of the point group on these collections of displacement vectors is then determined. The resulting combination is a *reducible representation,* which can then be resolved into a combination of *irreducible representations* by a simple mathematical procedure. Each irreducible representation describes a unique set of transformations of the molecule under each of the operations of the point group, each operation identifying, for example, whether or not a displacement along a given bond within the molecule remains in phase or out of phase when transferred to another (identical) bond in the same molecule. Consequently, the symmetries of each of the normal modes are determined.

In the example below, the symmetries of the normal modes of iodomethane (CH_3I) are determined. The molecule has C_{3v} point group symmetry, the operations of which are E (the identity), two C_3 (threefold) rotation axes, and three σ_v (vertical, containing the principal axis) mirror planes. Defining the principal axis as z, collinear with the C_3 axes, Cartesian displacement vectors are placed on each atom. The effect of each operation of the point group on the full set of Cartesian vectors is then determined, that is, the transformation of each of the x, y, and z vectors is calculated for each atom under the operations of the point group. The sum of these values under each class of operation in the point group then gives the reducible representation, as shown below:

C_{3v}	E	$2C_3$	$3\sigma_v$
χ(15 x, y, z vectors)	15	0	3

In this example, this reducible representation reduces to irreducible representations of $4A_1 + 1A_2 + 5E$ using conventional group theory methods. However, the inclusion of all three degrees of freedom for each atom means that this set of symmetry values accounts for the translations and rotations of the molecule as well as the vibrational normal modes. These nonvibrational degrees of freedom are eliminated by reference to the character table, which for C_{3v} reveals that the three translational degrees of freedom have $A_1 + E$ symmetry, while the three rotational degrees of freedom have $A_2 + E$ symmetry:

Removing these reveals the symmetries of the vibrational degrees of freedom (the normal modes) to be $3A_1 + 3E$. A final check of the numbers shows that this accounts for a total of nine normal modes (E symmetries are doubly degenerate, accounting for two modes simultaneously).

Once the symmetries of the normal modes have been established, the activity of the normal modes in the infrared spectrum can be determined. As described previously, not all modes will give rise to

C_{3v}	E	$2C_3$	$3\sigma_v$	Rotations and translations	Cartesian axes and their products
A_1	1	1	1	T_z	z; $x^2 + y^2$; z^2
A_2	1	1	−1	R_z	
E	2	−1	0	(T_x,T_y); (R_x,R_y)	(x,y); (xz,yz); $(x^2 - y^2)/\sqrt{2}$

an appropriate dynamic dipole change. For energy levels characterized by wavefunctions Ψ_i and Ψ_f, a nonzero transition dipole moment will only arise if the expectation value of the dipole moment operator for the transition is nonzero, that is,

$$\mu_{fi} = \int_{-\infty}^{+\infty} \Psi_f^* \hat{\mu} \Psi_i . \mathrm{d}\tau \neq 0 \qquad (26.17)$$

For this to be the case, the symmetry product of the wavefunctions and the operator should contain the totally symmetric irreducible representation in the point group of the molecule, that is,

$$\Gamma(\Psi_f) \times \Gamma(\mu) \times \Gamma(\Psi_i) \supset A, A_1, A', A_g, \cdots \qquad (26.18)$$

There are a range of procedures for this, which rely upon a knowledge of the symmetries of the various components. For $v = 0{-}1$ transitions (fundamental), the ground state wavefunction Ψ_i is totally symmetric, for example, A_1 in C_{3v}. The final state wavefunction Ψ_f has the symmetry of one of the normal modes, that is, taken from the set of symmetries determined in the example above. The dipole moment operator has the same symmetry as the x, y, and z axes in the point group of the molecule, for example, $A_1 + E$ in C_{3v}, as shown in the character table.

The problem generally simplifies further, since multiplying any symmetry species by the totally symmetric irreducible representation has no effect, for example, in C_{3v}, $A_1 \times E = E$. Consequently, it is only necessary to consider the symmetry of the normal mode and of the dipole operator, that is, to find out if $\Gamma(\Psi_f) \times \Gamma(\mu) \supset A, A_1, A', A_g$, and so on. The process of identifying whether a vibrational transition is infrared active therefore involves determining the molecular point group and identifying the symmetries of the normal modes and of the x, y, and z axes. Where the vibrational normal mode symmetry is the same as one of the axes, the vibration is infrared active. In the iodomethane example, all of the vibrational normal modes are infrared active.[1] Further information on these procedures can be found in Atkins and de Paula (2009) and Vincent (2001).

26.1.4
Gas-Phase Spectra and Rotational Fine Structure

The foregoing discussion has dealt entirely with transitions between vibrational energy levels. However, transitions between rotational levels can also occur simultaneously. As described elsewhere, rotational energy levels typically have spacing of the order of a few cm^{-1}; hence, in cases where natural linewidths are narrow (such as in low-pressure gases of simple molecules), rotational fine structure can be observed. In infrared absorption spectra, this structure is observed as a series of fine lines corresponding to a change of +1 in the vibrational quantum number and ±1 in the rotational quantum number. The intensity and extent of this rotational fine structure depend upon the population of the rotational energy levels in the vibrational ground state (the spacing of the rotational levels is small; hence, the Boltzmann distribution of population in the rotational energy levels typically extends to $J = 15$ or more). A fuller description is given in Hollas (1992).

---

[1] The procedure also applies to the determination of normal mode activity in vibrational Raman spectroscopy, except that the comparison is made between the symmetries of the normal modes and those of the polarizability operator α, which corresponds to the symmetries of the products of any two Cartesian axes. These are also normally shown in character tables. For molecules possessing a center of inversion, infrared and Raman activity are mutually exclusive.

26.2
Measurement of Infrared Vibrational Spectra

26.2.1
Principles of Infrared Spectrometry

The measurement of absorption spectra requires a light source emitting the appropriate range of frequencies, a dispersing element to separate the different frequencies of light, and a detector that responds quickly over the appropriate range of frequencies. At any particular frequency, the incident light intensity I_0 and the transmitted light intensity I are related to the amount of absorption by the sample via the Beer–Lambert law:

$$-\log_{10}\left(\frac{I}{I_0}\right) = \varepsilon c \ell \tag{26.19}$$

where ε is the molar absorption coefficient (meter square per mole), c is the concentration (mole per cubic meter), and ℓ is the path length (meter). The dimensionless logarithm term on the right-hand side (RHS) of Eq. (26.8) is the *absorbance*, A, a dimensionless quantity. Infrared spectra are usually presented as a graph of absorbance versus wavenumber.

As an alternative to absorbance, spectra can be presented as percentage *transmittance*, $\%T$.

$$\%T = \frac{I_0 - I}{I_0} \times 100 \tag{26.20}$$

Clearly, a transmittance of 100% represents no absorption, while a transmission of 10% represents an absorbance of 1.0. This measurement arose historically because transmittance is easier to measure experimentally in dispersive (diffraction grating) instruments. However, absorbance is linear in concentration and path length and is generally preferred for quantitative work.

26.2.2
Instrumentation and Spectral Processing

The basic requirement for benchtop infrared spectroscopy comprises a polychromatic infrared light source, a dispersion method to separate out the individual frequency components, and a suitable detector. In most instruments, infrared light is generated with a blackbody source optimized for output in the mid-infrared. These are generally electrically heated, low-current incandescent devices. Output characteristics of various sources in common use for mid- and near-infrared spectroscopy are reviewed in detail by Buijs (2002).

26.2.2.1 Interferometry in Infrared Spectroscopy

Originally, infrared spectrometers utilized rock salt prisms to disperse the frequency components, eventually moving to diffraction gratings for more flexible operation and improved longevity of the components (Workman, 1998). As for all grating-based monochromators, there are significant trade-offs between the frequency bandpass (a function of the slit widths used at the input and output of the monochromators) and the optical throughput. As a consequence, the measurement of high-resolution infrared spectra (of gases, for instance) was

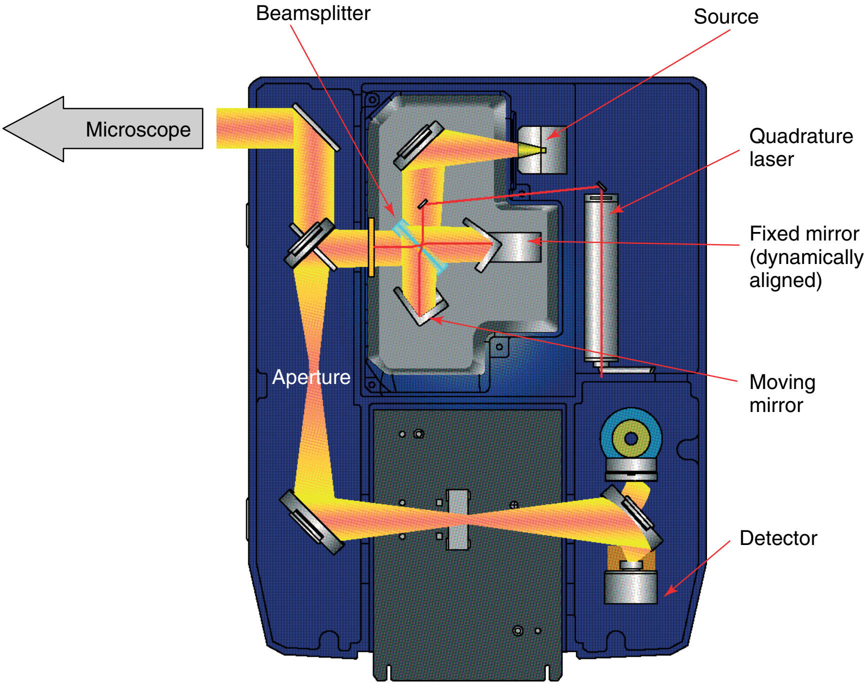

Fig. 26.4 Schematic representation of a Michelson interferometer in a commercial FTIR spectrometer. Reproduced by kind permission of JASCO UK.

a considerable experimental challenge. However, with the advent of improved computational facilities in the 1970s, methods based upon interferometry became the norm. The basic principles of interferometry as applied to infrared spectroscopy involve the separation of the source radiation into two beams using an appropriate beamsplitter. These beams then pass along separate light paths before being recombined (usually at the same beamsplitter). Any path difference experienced by the two beams leads to interference upon recombination, with different frequency components combining with different phases. The superposition of these interferences is recorded at discrete (normally equally spaced) intervals of path difference δ to give a path-difference-dependent signal referred to as an *interferogram*. The most common apparatus used to perform this separation and recombination is the Michelson interferometer, shown schematically in Figure 26.4, although other possibilities are also in widespread use. In many modern spectrometers, the fixed mirror is dynamically aligned with the moving mirror for improved stability and precision. This is normally affected using piezo-electric transducers. The output interferogram, $I(\delta)$, is measured using a detector operating over the appropriate frequency range. After digitization, the interferogram is inverted using a discrete Fourier transform to produce a frequency-domain spectrum, $I(\nu)$, and hence the common acronym *FTIR* (*Fourier-transform infrared*) spectrometry. The spectral resolution (i.e., the spacing between the data points) in the computed spectrum is inversely related to the maximum path difference $\delta_{\max}$ in the interferometer. Typical general purpose benchtop FTIR spectrometers with a maximum resolution of 0.5 cm^{-1} therefore require path differences of 2 cm, which is easily attainable with relatively unsophisticated apparatus. The path difference between the two optical paths is usually measured to an appropriate precision by interference from two orthogonally polarized HeNe laser beams by quadrature. Increased resolution requires very high mechanical stability over path lengths that can be several meters. Further experimental details can be found in sources such as Griffiths and de Haseth (1986) and Jackson (2002).

The acquisition of intensity data in the temporal domain and its transformation into the spectral domain brings a number of interesting features and artifacts that need to be understood and in many cases incorporated into the post-acquisition processing of the resultant data. A typical interferogram is shown in Figure 25.5(a). The mechanical, discrete nature of the temporal domain data acquisition leads to a range of effects. First, the path differences in the two optical paths are usually created by movement (either translation or rotation) of an optical component (usually a mirror) from a path difference of zero to $\delta_{\max}$ at a certain mirror velocity The detector, therefore, observes a signal that contains interference components modulated over a range, with the highest frequency component being modulated at the highest rate. The detector, therefore, needs to be capable of responding to changing signal intensity at this maximum rate. Furthermore, the sampling of this highest frequency component needs to be made at least twice its frequency (according to the Nyquist criterion). This requires suitably optimized amplification and digitization electronics. The collected data also contain a further artifact of scanning δ with a moving optical component: the data are usually "chirped" in the direction of the movement. This effect can be removed by a process called *phase correction*. In practice, interferograms are often sampled double-sided (i.e., from $-\delta_{\max}$ to $+\delta_{\max}$) and in both forward and backward directions, with the information required for effective phase correction being obtained from the asymmetry of the interferogram either side of the zero path difference point (Griffiths and de Haseth, 1986).

The second substantial effect of the acquisition of temporal domain data over a limited range of δ occurs upon Fourier transformation of the data to the temporal domain. Collection of data from $\delta = 0$ to $\delta_{\max}$ is effectively the equivalent of multiplying the full, infinite set of temporal domain data (from $\delta = 0$ to ∞) by a boxcar function (i.e., unity from $\delta = 0$ to $\delta_{\max}$ and 0 beyond $\delta_{\max}$). Consequently, the lineshape observed in the spectral domain is a convolution of the Fourier transform of the temporal data with the Fourier transform of a boxcar function. For example, a pure sine wave signal would transform to a delta function from infinite data, whereas in practice a truncated sine wave (from $\delta = 0$ to $\delta_{\max}$) transforms to a spectral feature with both a finite bandwidth and with additional side-lobes. This effect can be significant for spectral data containing sharp, narrow features (especially in gas-phase spectra). It can be significantly reduced by a process referred to as *apodization*, where the recorded temporal data are

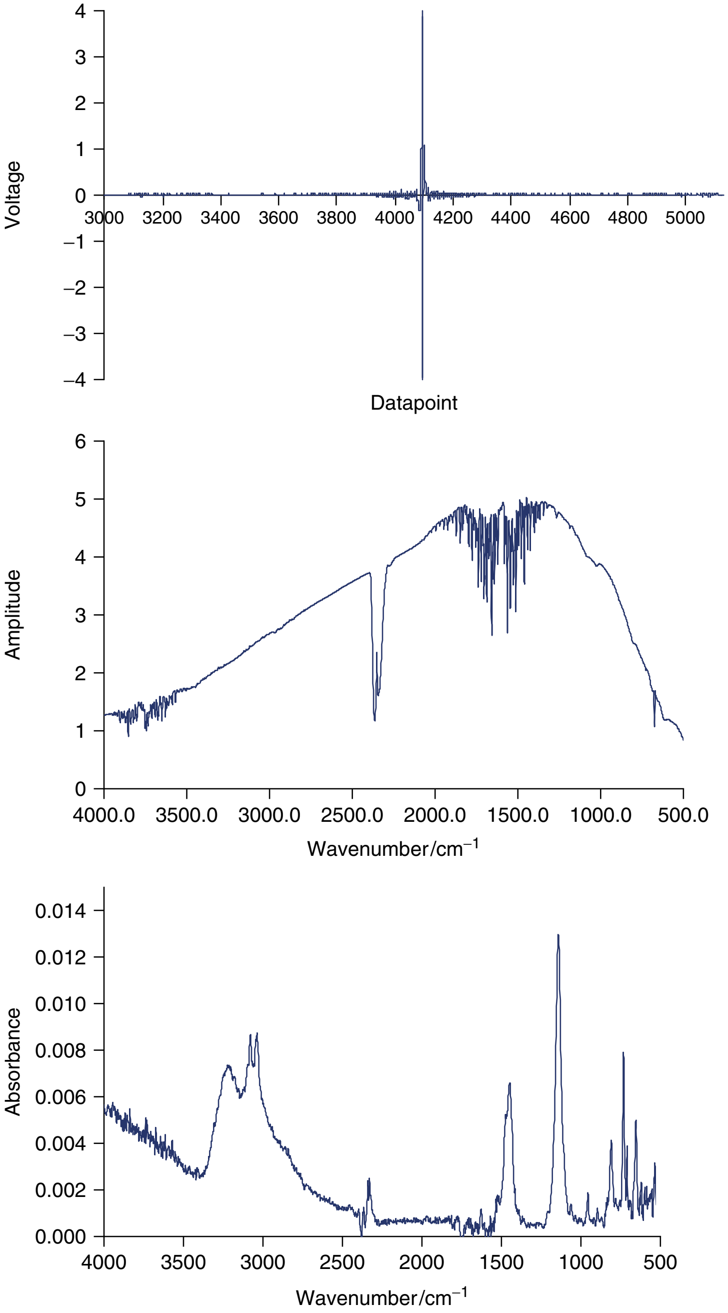

Fig. 26.5 (a) Example of a typical interferogram; (b) single-beam spectrum resulting from the Fourier transform; and (c) absorbance spectrum resulting from the ratio of two single-beam spectra, one containing background information only and one containing additional spectral information.

multiplied by a specific function with a less intrusive spectral domain lineshape. These and other FT-related artifacts are described in more detail in Griffiths and de Haseth (1986) and Kauppinen and Partanen (2001).

A final processing technique, which is frequently encountered, is zero-filling, in which the temporal interferogram data are extended by the addition of further data points (with zero intensity) beyond $\delta_{\max}$. This has the effect of placing additional spectral domain data points between the real values. The additional values are interpolations between the real values, smoothing the data, although they clearly do not add any additional information.

In practice, Fourier-transform-based methods have three main advantages over conventional, dispersive methods. First, the data points are measured temporally with a high degree of accuracy; therefore, spectral accuracy (frequency precision) is high in the computed spectrum. Furthermore, the throughput of light is not limited by the presence of slits as for monochromator-based methods. This leads to much higher working signal levels at the detector, with improved signal-to-noise (S/N) ratios. S/N ratios are also improved by the multiplex advantage, since all frequency components are effectively sampled together. In general, the S/N in FTIR spectra is noise limited and can be improved by the coaddition of interferograms before processing. Typically, the S/N improvement scales with the square root of the number of scans.

26.2.2.2 **Processing of Infrared Spectra**

As described above, FTIR methods therefore involve collection of data as interferograms and subsequent processing to produce a single-beam spectrum, an example of which is shown in Figure 26.5(b). During the course of this processing, a number of mathematical procedures can be performed in order to improve the visual appearance of the output, remove artifacts, and optimize the spectrum. Following the Fourier transformation of the interferogram to produce a single-beam spectrum, the simplest operation is the ratioing of two single-beam spectra to produce an absorbance spectrum. This is necessary because the single-beam operation of an interferometer-based spectrometer produces spectra that are a convolution of the source output profile, the detector response profile, and any limiting optical transmission effects from components in the light path (such as beamsplitters, mirrors, lenses, and sample-handling apparatus). Figure 26.5(b) shows this overall response profile with absorptions from CO_2 and water vapor within the optical path. The absorbance (or transmittance) spectrum of a given sample is obtained from the ratio of single-beam spectra obtained in the presence and absence of a sample. This operation is performed in software with various interventions including the reduction or elimination of water vapor and CO_2 spectral features. Figure 26.5(c) shows a typical absorbance spectrum obtained in such a manner.

A variety of more sophisticated postprocessing methods are commonly available in the software accompanying commercial benchtop FTIR spectrometers for further processing of the absorbance (transmittance) spectra thus obtained. This typically ranges from basic mathematical processing such as spectral subtraction/addition and smoothing to more advanced methods such as Fourier deconvolution and spectral bandshape fitting. Databases of infrared spectra are also widely available, and algorithmic methods for comparison of spectra with these library references are used to suggest a range of possibilities and calculated goodness of fit. At a more sophisticated level, chemometric software is also increasingly available for sophisticated quantitative analysis. The specific details of these methods and packages vary widely between manufacturers. Details of these and other related methods can be found in the ''Quantitative Analysis'' section of (Chalmers and Griffiths, 2002, vol. 3).

26.2.2.3 Infrared Detectors

The detection of infrared radiation in interferometric applications requires apparatus that can detect photons over the relevant mid-infrared range and which is also capable of registering changes in the intensity of such radiation at the maximum modulation frequency of the output of the interferometer (Theocharous and Birch, 2002). In conventional FTIR spectrometers, this is normally achieved using either a bolometer or a photon detector. The commonest example of the former used deuterated triglycine sulfate (DTGS) as the active medium. Thermal changes in the detector upon incidence of infrared radiation are measured electrically and amplified. The response of this material is such that only relatively slow modulation frequencies (a few kilohertz) are possible, but the main advantage is that the linearity of such detectors is high. For this reason, they are the most common choice for quantitative work.

For more sensitive detection of lower levels of infrared radiation, semiconductor-based photon detectors are also in common use. These rely upon the presence of an appropriate bandgap in the detection material, with detection in one form or another of the electrons excited by interaction with the incident infrared photons. To prevent thermal excitations, it is necessary to cool the materials, usually by placing them in thermal contact with a liquid nitrogen reservoir. Although highly sensitive, such detectors have an inherently nonlinear response and care should be taken in quantitative work. The main usage of such detectors is in applications where low light levels occur, especially in sampling accessories with low light throughput. Photon detectors respond much more rapidly to changes in infrared intensity; hence, considerably higher modulation frequencies are accessible. This permits much higher scan rates within the interferometer. The most common material used in modern detectors is mercury cadmium telluride (MCT). There is a trade-off between the range of frequency response of MCT detectors and the sensitivity; with careful bandgap tuning, ''wide band'' MCT detectors can be made to operate across most of the mid-infrared range, although detectivity falls markedly and cost increases. For specific applications in a restricted range within the mid-infrared, other materials such as indium antimonide (InSb) are also available.

26.2.3
Basic Transmission Sampling Methods

In its simplest form, infrared spectroscopy relies upon the preparation of samples through which the infrared beam from a spectrometer can be passed with minimal loss. In some cases, this requires the use of accessories for the presentation of samples to the infrared beam (Belton and Wilson, 1990). For appropriately tractable samples, infrared spectra can be obtained by direct transmission of light. Typical values of the molar absorption coefficient ε require the use of either low concentrations or short path lengths to keep measured absorbance values in the linear region (below ca. 1.2). In practice, an appropriate amount of material is normally supported between two accurately spaced optical windows. The choice of appropriate window material largely depends on application, but some of the most common are shown in Table 26.1, along with their range of practical transmission and also some limiting physical properties.

26.2.3.1 Gases

Apparatus for the acquisition of the infrared spectra of gases normally involves path lengths of 10 cm and upward. High-resolution infrared spectra of gases are often recorded at reduced pressure to reduce the effects of collision-induced (pressure) line broadening, requiring the use of extended path lengths to attain appropriate individual signal levels. A schematic of a typical cell is shown in Figure 26.6. Multiple passes are achieved using White multipass optics, with commercial accessories available with optical path lengths up to 20 m.

26.2.3.2 Liquids

Thin films are often necessary for the acquisition of transmission infrared spectra from liquids. For pure liquids, cells with accurately spaced windows are widely available, with path lengths of the order of a few microns upward. Spectra can also be obtained from solutions, again with an appropriate choice of path length. The contrasting need to avoid solvent absorptions blacking out (reaching absorbance values greater than 1.2) while achieving suitable signals

Tab. 26.1 Properties of infrared transparent materials in common usage.

Material	Transmission range/cm^{-1}	Properties
NaCl	40,000–625	Very soft, easily fogged by water vapour; low cost
KBr	40,000–400	Very soft, easily fogged by water vapour; low cost.
ZnSe	17,000–720	Hard and brittle crystal, pale yellow in colour; sometimes known as Irtran-1.
KRS-5	20,000–250	Very soft, deforms under pressure; soluble in bases and insoluble in acids. Toxic.
CaF_2	77,000–1,110	Strong, acid and alkali resistant; withstands high pressure; insoluble in water. Poor range.
Si	8,300–660	Very hard but quite brittle; relatively inert; insoluble in water.
Ge	5,500–600	Very hard and brittle with a high refractive index (4); insoluble in water.
Diamond	25,000–33	Very hard, resistant to most types of chemicals. Phonon bands around 1900–2600.

from dilute solutes requires a degree of flexibility.

26.2.3.3 Solids

Infrared spectra of solid materials are accessible in a variety of ways, usually obtained after grinding the relevant solid to a fine powder and suspending the particles thus obtained in a suitable medium. Hydrocarbon or halocarbon oils were traditionally used for this purpose, the most common being Nujol.

The resulting oily suspension is then placed between two transparent windows and mounted in a holder in the sample compartment of a spectrometer. Blank windows are normally used as a background in order to nullify the effects of scattering and reflection from imperfect windows. The main intrinsic absorption bands in Nujol arise from aliphatic CH_2 and CH_3 features and thus the material is of little use for detailed examination of organic material containing such functionality, but useful spectral windows are to be found between these resonances. Halocarbon alternatives to Nujol are frequently used to access the CH stretching regions, although these materials do have absorptions in other regions.

A more practical alternative in many organic applications are pressed discs of KBr. In this method, the sample is ground to a fine powder and mixed with dry, powdered KBr and compressed in a die with a hydraulic press. The particles of KBr flow under such pressure and a semitransparent disc is obtained. With careful control of amounts of KBr and sample, this method can be used quantitatively. A significant advantage over mulls is the absence of absorption bands due to the suspending agent, with the principal problem being the hygroscopicity of KBr, which can lead to significant water uptake unless due care with handling and storage of the materials and discs is taken. Another potential problem with this method when applied to inorganic and organic salts is the possibility of ion exchange (e.g., Br^-) between the matrix material and the sample. Care must also be exercised when studying organic solids that exhibit polymorphism, as the pressure required to form KBr discs may also be sufficient to drive a polymorphic phase transition, with a concomitant effect of the infrared spectra of the material. These and other sampling methods in common use are reviewed in detail in Coates (1998), Belton and Wilson (1990), and Hannah (2002).

26.2.4
Reflection-Based Sampling Methods

Reflection methods are finding increasing application in physical sciences as a way of examining materials with a minimum of sample preparation. Using modern sampling accessories, it is possible to acquire infrared spectra from internal, external, and diffusely reflected infrared radiation, although there are many diverse and unusual perturbations to the spectra in reflection configurations that need careful consideration.

26.2.4.1 Specular Reflection

Specular reflection refers to reflection from relatively flat materials such that the angles of incident and reflected beams are the same with respect to the surface normal. The optics of light reflection and transmission from interfaces between both absorbing and nonabsorbing media alike are well understood and accurately described by Maxwell's equations or by a Fresnel equation formalism (Heavens, 1955; McIntyre and Aspnes, 1971). Generally, the reflection behavior is different for light polarized perpendicular and parallel to the plane of incidence (defined as the plane that includes the incident electromagnetic beam and the surface normal), referred to as s- and p-polarization, respectively. In general, the optical properties of each medium are described by their complex refractive index,

$\mathbf{n}$, or the dielectric constant, $\boldsymbol{\varepsilon}$, that is,

$$\mathbf{n} = n - ik \tag{26.21}$$

where n is the refractive index and k is the absorption coefficient. When $k = 0$, the refractive index is real in all cases. Similarly, the dielectric constant has real and imaginary components:

$$\boldsymbol{\varepsilon} = \varepsilon' - i\varepsilon'' \tag{26.22}$$

The two are related.

$$\varepsilon' = (n^2 - k^2)$$
$$\varepsilon'' = 2nk \tag{26.23}$$

For the interface between two phases i and j, the Fresnel coefficients for s- and p-polarization are given as

$$\mathrm{r}_{ij}^{s} = \frac{\mu_j \xi_i - \mu_i \xi_j}{\mu_j \xi_i + \mu_i \xi_j}, \quad \mathrm{r}_{jk}^{p} = \frac{\varepsilon_j \xi_i - \varepsilon_i \xi_j}{\varepsilon_j \xi_i + \varepsilon_i \xi_j} \tag{26.24}$$

where μ_j is the magnetic permeability (ca. 1 in the mid-infrared) for phase j. The function ξ_j for each interface is effectively a complex angle of incidence/refraction term on the interface $(j-1)|j$.

$$\xi_j = \sqrt{\mathbf{n}_j^2 - \mathbf{n}_1^2 \sin^2 \theta_1} \tag{26.25}$$

where θ_1 is the angle of incidence of the light upon the first layer and $\mathbf{n}_j$ is the complex refractive index of the phase j (for multilayer systems, discussed later). The substrate reflectance can be determined as a function of θ using Eqs (26.4) and (26.5). Figure 26.7 shows a comparison of the reflectivity of a typical nonabsorbing dielectric, silicon ($n_{\mathrm{Si}} = 3.44$, $k_{\mathrm{Si}} = 0$), and a metal, platinum ($n_{\mathrm{Pt}} = 3.0$, $k_{\mathrm{Pt}} = 30.0$) (Horn, 1998).

There are large differences between these examples in several ways, which affect the nature of the optical configuration required to acquire spectra from the interfacial region. Most noticeably, the reflectivity of silicon is lower than for a metal (except at 90°) for both polarizations, starting from around 35% at normal incidence. The s-polarized reflectivity rises monotonically from its normal incidence value to 100% at 90° (i.e., for a given angle, less light will be reflected from dielectrics than from metals), whereas the p-polarized reflectivity of silicon falls to zero at the polarizing or Brewster angle θ_B, where

$$\theta_B = \tan^{-1}\left(\frac{n_{\mathrm{Si}}}{n_1}\right) \tag{26.26}$$

When a substrate has frequency-dependent optical constants (i.e., absorption bands), this behavior can be used to collect reflectance spectra. The reflectivity of the substrate is modified across the absorption band by absorption and by dispersion due to the changing refractive index. This gives rise to characteristic lineshapes in reflectance spectra, an example of which is shown in Figure 26.8. The frequency-dependent n and k behavior can be separated out mathematically using a Kramers–Kroenig transform, usually a built-in feature of most modern spectrometer software packages. The k-spectrum thus obtained is directly analogous to the absorption spectrum of the material (Willis and Powell, 1990).

26.2.4.2 Reflection–Absorption

In the case of metals, the reflectivity of the interface can be used to record infrared spectra of adsorbed monolayers and condensed ultrathin films. It was first demonstrated theoretically (Greenler, 1966) and then practically (Pritchard and Sims, 1970) that, under certain

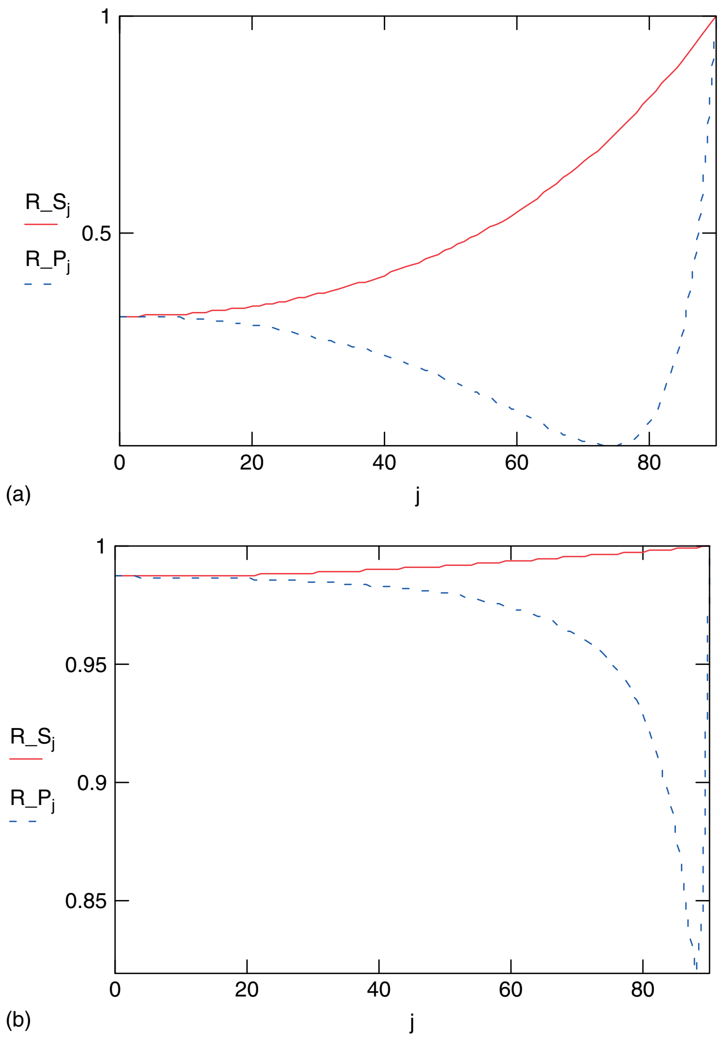

Fig. 26.7 Modeled reflectivity of the vacuum/substrate interface for (a) a typical metal with optical constants $n = 3.0$, $k = 30.0$ and (b) a typical nonabsorbing dielectric with $n = 3.44$, $k = 0$.

circumstances, infrared spectra of monolayers in metals could be obtained in a "reflection–absorption" configuration. The method, referred to variously as *reflection–absorption infrared spectroscopy* (*RAIRS*) or infrared reflection–absorption spectroscopy (IRRAS), has subsequently been used extensively to study adsorption and reaction of a substantial range of adsorbates on a variety of transition metal surfaces that are of interest in catalysis, corrosion, and electrochemistry. Practically, the experiment requires light to be incident upon the metal surface containing the adsorbate at a grazing incidence. This behavior

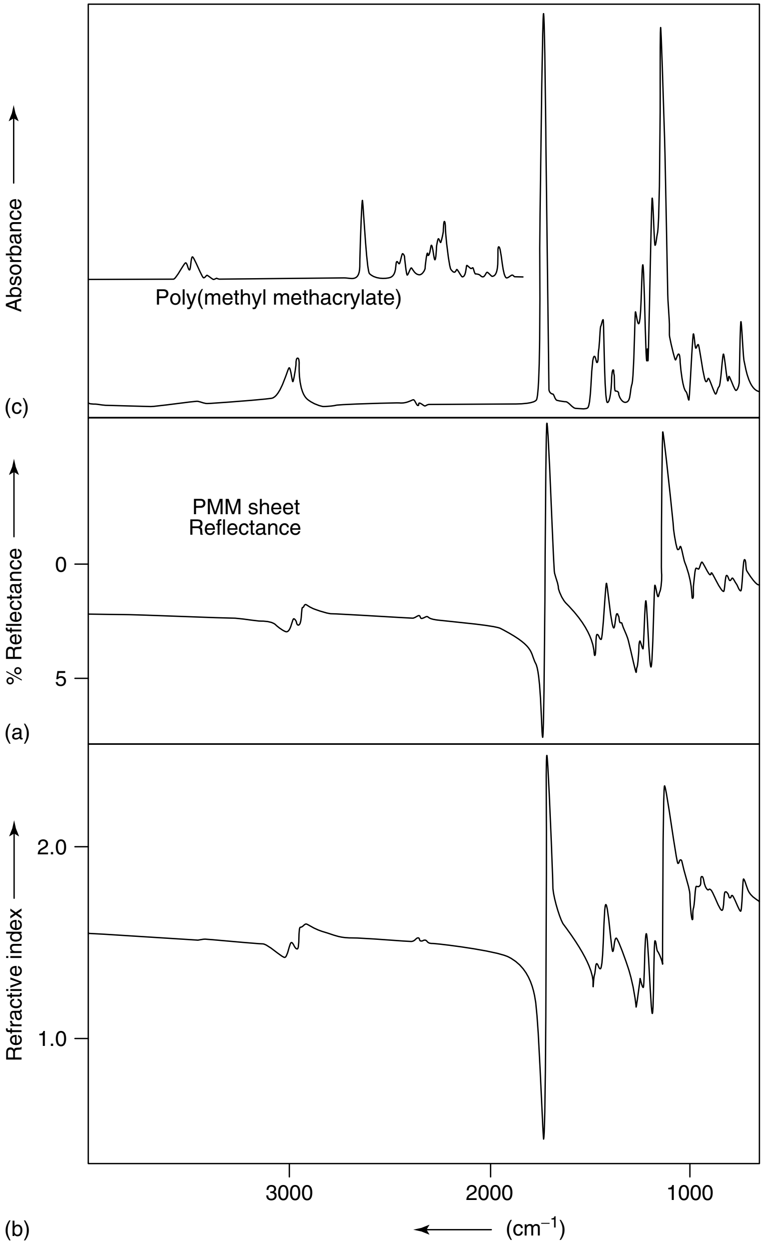

Fig. 26.8 Reflectance spectrum of poly(methyl methacrylate), showing deconvolution of the pure reflectance (a) into the *n*- (b) and *k*- (c) spectral components. Reproduced from (Willis and Powell, 1990.)

again has its origins in the optics of the vacuum/metal interface, and using an extension of the Fresnel model described above it can be shown that only vibrations with a component of their dynamic dipole, which is perpendicular to the surface, are seen. Grazing incidence is therefore necessary both to maximize the surface-normal component of the infrared beam and to interact favorably with the optical properties of the surface. Optically, coupling of the dynamic dipole of vibrational motion parallel to the surface to the infrared radiation is suppressed. A phenomenological description of this behavior was first given by Pearce and Sheppard (1976) who invoked the idea of ''image charge'' in the surface to show that vibrational dynamic dipoles parallel to the surface cancel out, whereas those perpendicular are reinforced, leading to the so-called metal-surface selection rule (MSSR). A detailed description of the optics and practicalities of RAIRS measurements are given elsewhere by Hollins (2000) and Bradshaw and Schweizer (1988).

Typical, RAIRS is used to monitor the adsorption of gaseous species on reactive metal surfaces. This frequently involves the use of a highly polished metal single crystal or polycrystalline metal film as a substrate, normally supported in ultrahigh vacuum to prevent adsorption of contaminants. The infrared beam from a spectrometer is coupled into the vacuum chamber through an infrared-transparent window and is incident upon the sample at a highly grazing angle. The reflected light is recollimated and focused onto a detector externally (in some cases, the source is the external component rather than the detector).

The MSSR is ideal for the identification of adsorbate geometries on metal surfaces, since only those vibrational modes with transition dipole moments perpendicular to the surface can be observed in the resulting RAIR spectrum. If accurate assignment of the normal modes to specific directions with respect to the molecular axes is possible, the presence or absence of individual modes can thus be used to deduce orientation with respect to the surface. For example, the symmetric C—H stretching mode of a methyl group attached to another moiety has its transition dipole oriented the C_3 rotation axis, whereas the antisymmetric CH stretch is polarized in a plane perpendicular to the axis. Simultaneous absence of antisymmetric mode and presence of the symmetric mode in the RAIR spectrum would therefore imply that the C_3 axis for the methyl group is perpendicular to the plane of the surface. The opposite configuration, that is, where the C_3 axis is parallel to the surface, would reverse the activity of the modes in the resulting RAIR spectrum. For whole molecules, the chemical structure of the adsorbates and their orientation with respect to the surface can often be determined by examining the positions and intensities of the absorption bands in comparison to reference spectra from isotropic bulk samples and gases. As an example, Figure 26.9 shows a RAIR spectrum from the adsorption of methyl silane on Cu(111) at 50 K. In this case, the adsorbate remains intact but lies predominantly with the Si–C axis parallel to the surface in the monolayer. Increasing coverage beyond a single monolayer results in a more disordered multilayer with a range of orientations more redolent of an amorphous thin film or liquid (Menard, Tear and Horn, 2008). Information such as this can be vital to the development of the understanding

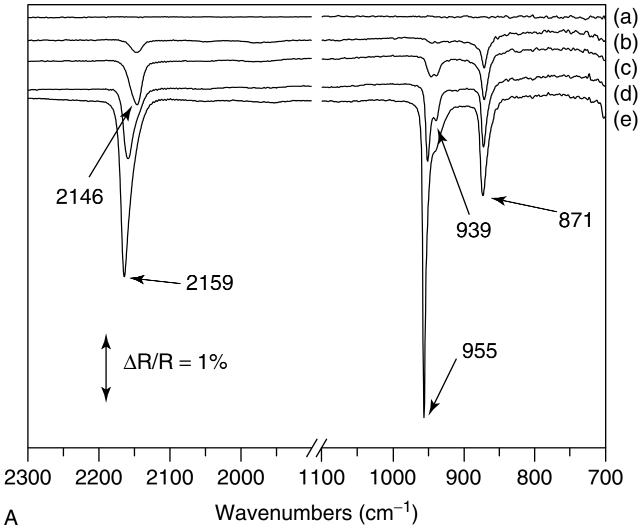

Fig. 26.9 Reflection–absorption infrared spectrum of CH_3SiH_3 (methyl silane) adsorbed on a copper Cu(111) surface at 50 K. The spectra show increasing coverage of the surface from (a) to (e), in which monolayer features are first observed, followed by multilayer features. Under the terms of the metal-surface selection rule, the bands at 870 and 2148 cm^{-1} indicate that the molecule lies with its C_3 axis flat to the surface in the monolayer; further, as the material is deposited, a disordered multilayer forms and many more bands become active. Taken from (Menard, Tear and Horn, 2008).

of catalytic processes at a microscopic level. In less specialized experiments, RAIR spectra can also be obtained from self-assembled monolayers and Langmuir–Blodgett films on metal surfaces under ambient conditions (Horn, 1998). In general, care should be taken in the interpretation of RAIR spectra from thicker films as the optical properties of the ambient phase/thin layer/substrate become less straightforward with increasing thickness. This can lead to a range of band position and shape perturbations, for instance, through the excitation of longitudinal optical resonances (Berreman, 1963). However, with a detailed knowledge of the directionality of the vibrational dynamic dipole moments, orientational information can be extracted with a very high degree of sophistication (Allara and Nuzzo, 1985).

RAIR spectra can also be obtained from nonmetallic surfaces under certain conditions. To a large extent, the MSSR does not apply except for some semimetallic substrates, with vibrational dynamic dipoles in all orientations being observed (although with different intensities). Once again, the behavior is adequately described by a simple Fresnel model. Once again using silicon as a typical example covered with a 1-nm film of isotropic adsorbate (i.e., dynamic dipoles in all directions), the following behavior is observed at the peak of an absorption band. At normal incidence, both the s- and p-polarized responses are equal (as they must be, since both are parallel to the surface at normal incidence) and negative in absorbance units, that is, the presence of an adsorption band results in an *increase* in surface reflectivity compared to the clean surface. With increasing angle, the s-polarized RAIRS response falls monotonically reaching zero at grazing incidence. The p-polarized behavior falls, crosses zero, becomes large and positive at angles of incidence just below θ_B, inverts to become large and negative above θ_B, and again reaches zero at grazing incidence. The p-polarized behavior is largely determined by the reflectivity of the underlying substrate, with the discontinuity around θ_B being a "divide by zero" error. Figure 26.10 shows this behavior schematically.

Reflection–absorption is not confined to gas/substrate interfaces. Recently, there has been much progress in the acquisition of infrared spectra from the surfaces of electrochemical cells or from substrates under high pressures of ambient gas. A number of methods are required to make this possible, largely due to strong absorptions by the electrolyte or gas. In the case of high gas pressures, this can be achieved using the s-polarized (non-interacting) response of a surface as a normalizing signal. In this case, the s-polarized component contains information about the ambient absorption with no spectral information from the surface due to the MSSR rule. The p-polarized response contains the same (isotropic) absorptions from the electrolyte and also the p-polarized surface RAIR information. Polarization modulation and normalization to the s-polarized spectra again allows the gas-phase and

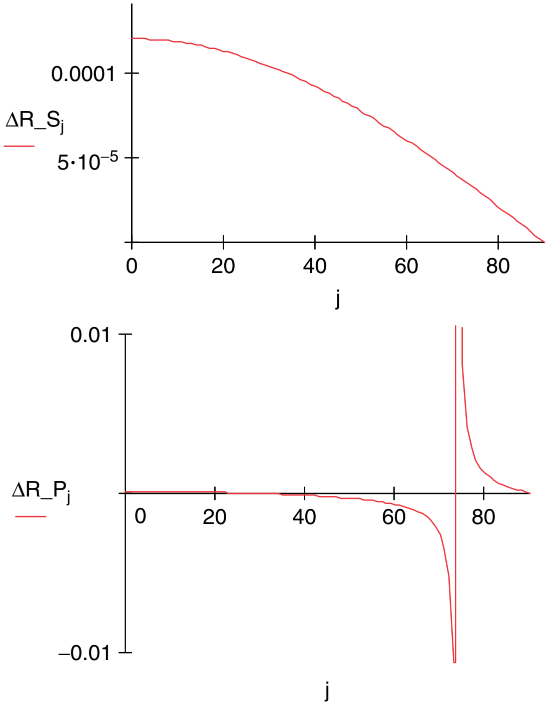

Fig. 26.10 Modeled reflectivity change due to the presence of a thin absorbing layer on a dielectric (silicon) surface as a function of angle of incidence for s- and p-polarized radiation.

surface components to be separated. For electrochemical surfaces, reduction of the ambient (electrolyte) absorption can be achieved using ultrathin electrolyte films above metal surfaces, although transport effects often dominate under such conditions. The use of thicker electrolyte layers requires the use of more advanced methods to remove the effect of electrolyte absorption. Normalized difference spectra are obtained as a function of potential, and the method is frequently referred to as *surface-normalized FT infrared spectroscopy*, (*SNIFTIRS*), and can be very sensitive to very small quantities of adsorbates on electrode surfaces (see, e.g., (Chen and Lipkowski, 1999)). Positive and negative-going bands are seen in the spectra, indicating adsorption and desorption of species from the surface. This differential reflectance behaviour can be modeled to obtain orientational information from the adsorbates under certain circumstances (Pettinger *et al.*, 2001).

In practical terms, accessories are available to fit within the sample compartment of conventional benchtop FTIR spectrometers for recording RAIR spectra from thin films on different substrates. The simplest are fixed angle devices using 80 or 85° for thin films on metallic surfaces. More sophisticated accessories incorporate the ability to change the angle of incidence. A schematic of such a device is shown in Figure 26.11.

26.2.4.3 **Diffuse Reflectance**

Powdered material, whether comprised of regular crystallites or random amorphous particles, scatters light in a range of directions. This light scattering arises from a range of sources, some of which contain spectroscopic information. Where the individual crystallite surfaces are optically flat, some of the scatter arises from specular reflection (from these flat surfaces in the sample), although the range of orientations of the crystallites means that the scattered light exits in all directions. For optically rough surfaces, the scatter is again diffuse. Both of these contributions may contain some spectroscopic information from resonant interaction with material at the surface of the particles, but the effects are usually relatively weak. From a spectroscopic viewpoint, the most useful component arises from light that has passed through the particles before escaping. This component is often internally reflected several times, and again, the scattered light is emitted randomly over a wide solid angle. During its transit through the particles, resonant absorption can occur; hence, comparison of this component to diffusely scattered light from a nonabsorbing reference sample may give considerable spectroscopic information.

The theory of diffuse reflectance (DR) has been described in detail elsewhere, with various structures and nomenclatures used to identify and quantify the contributions to the total collected diffuse scatter (Milosevic and Berets, 2002). The most common treatment is the Kubelka–Munk model, for which a relatively simple solution exists for the case of an infinitely (practically, a few millimeters in a suitable metal cup) thick sample. From an experimental viewpoint, the measurement of spectroscopic information from diffusely reflected light from a sample revolves around the separation of the diffuse specular reflection

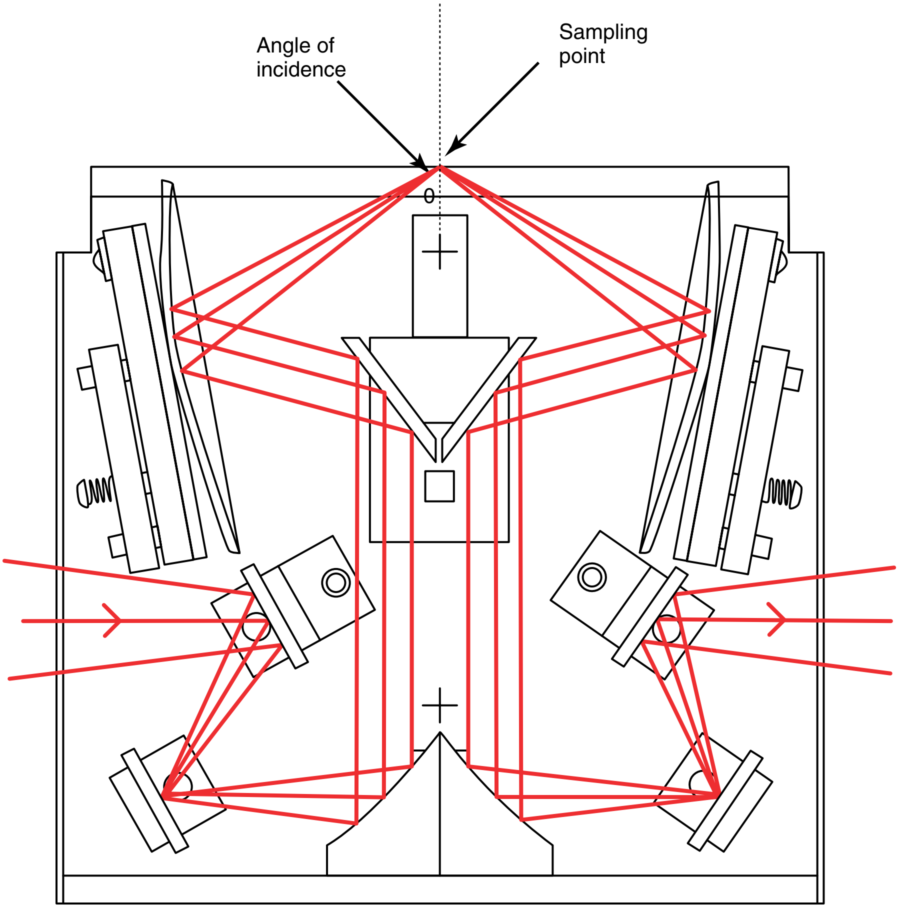

Fig. 26.11 Schematic of the optical path through a variable angle reflection accessory. Reproduced by kind permission of Pike Technologies.

from the internally reflected diffuse component. Practically, sampling utilizes a focused beam incident upon a cup containing the powdered sample. The diffusely reflected light is collected over a large solid angle using a specially shaped mirror, the purpose of which is to recollimate a maximal amount of the internally diffusely scattered radiation and return it to the light path of the spectrometer. The spectral parameter commonly obtained is R_∞, the ratio of the diffuse scatter as a function of wavenumber from a given sample and that from a powdered, nonabsorbing sample. From the Kulbelka–Munk model for an infinitely thick sample with minimal diffuse specular scatter, the absorption k and the scatter s are related to R_∞ such that

$$\frac{k}{s} = \frac{(1 - R_\infty)^2}{2R_\infty} \tag{26.27}$$

A number of sampling methods are in widespread use. The most common application simply requires a powdered sample to be placed in a cup at the focus point of the optics. However, in samples with very strong absorption bands, distortion occurs and it is necessary to dilute the powder. This is normally done by diluting the sample (typically to about 5%) in an inert matrix such as KBr. The sample remains loosely packed (compared to pressed KBr discs for transmission measurements) and thus there are fewer problems with pressure-induced effects on the sample. Another method for the preparation of samples for diffuse reflectance measurements utilizes a SiC disc, which is used to abrade material from otherwise intractable solid samples. The DR spectrum can be recorded directly from this disc, although the optical arrangement is far from the ideal Kubelka–Munk situation and is at best a qualitative measurement.

Quantitation in diffuse reflectance spectroscopy requires great care, as the effects of scattering from the matrix, concentration of the absorber, and dispersion in the optical constants of the sample are complex. For "ideal" powdered samples, the penetration depth of the radiation before diffuse scattering is dependent upon k, which means that diffuse reflectance measurements are particularly sensitive to weak absorptions, for which the spectroscopic path length is effectively longer.

The design of apparatus to collect diffuse scatted from powdered samples is nontrivial, and a number of designs are in use. Broadly speaking, the challenges are threefold: to illuminate the sample with as much incident radiation from the spectrometer as possible, to collect as much of the diffusely scattered light as possible, and to minimize the amount of diffuse specular reflection collected. There is a further trade-off between the solid collection angle and the area of the sample illuminated, which requires optimization in any optical configuration. The high sensitivity of Fourier-transform spectrometers is essential for diffuse reflectance measurements, as the restrictions on collection area and geometry, as well as the inclusion of various methods to reduce the specular scatter, reduce the throughput of diffuse reflectance accessories to as little as 5% of the total power. The optical configuration of a typical diffuse reflection accessory is shown in Figure 26.12. The accessory is located in the sample compartment of the spectrometer, intercepting the spectrometer beam and directing in onto specially shaped mirrors. The diffusely reflected light is collected and returned to the spectrometer light path.

In such a configuration, controlled environment chambers can be added at the sample point, allowing the investigation of reactions on particles of environmental and catalytic interest to be studied. Figure 26.13 shows a modified diffuse reflectance accessory used to observe the uptake of gas-phase NO_2 onto NaCl particles representative of material present in the atmosphere in the marine boundary layer. In this particular case, the adsorption process shows the formation of nitrate during in the reaction, which remains adsorbed onto the particle surface (Vogt and Finlayson-Pitts, 1994).

26.2.4.4 Attenuated Total Internal Reflection

The most significant development in the applicability of infrared spectroscopy to the widest variety of samples without significant preparation over recent years is the advent of attenuated total internal reflection (ATR) based methods. The ATR effect was first described by Newton in *Opticks*, and the seminal work by

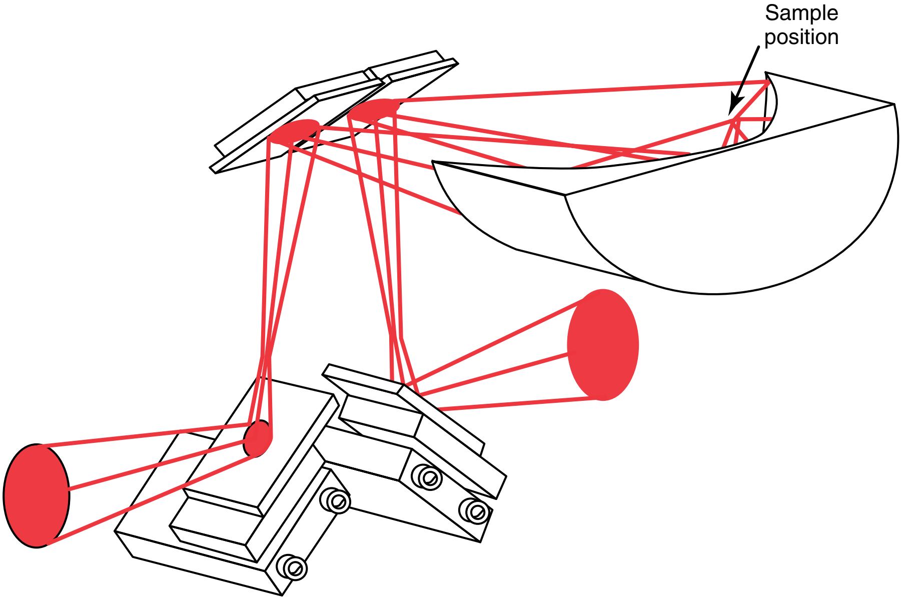

Fig. 26.12 Schematic of the light path through a typical commercial diffuse reflectance accessory. A single complex mirror directs the infrared beam onto the sample and collects the diffusely reflected light for return into the spectrometer light path. Reproduced by kind permission of Pike Technologies Inc.

Harrick (1967) in the 1960s set the groundwork for the wide-scale use of ATR methods in optical spectroscopy.

When light is incident upon the interface between two nonabsorbing media with refractive indices n_1 and n_2 from within that with the higher refractive index, total internal reflection is observed above a certain critical angle, θ_c, given as

$$\theta_c = \tan^{-1}\left(\frac{n_2}{n_1}\right) \tag{26.28}$$

For a germanium substrate in contact with a vacuum, $n_1 = 4$, $n_2 = 1$ and hence $\theta_c = 14°$ from the surface normal. Below this angle, a proportion of the light is internally reflected and the remainder is transmitted through the interface. The variation of the internal component with angle of incidence is again adequately described by the Fresnel equations, as shown in Figure 26.14(a). Subtly different angle-dependent behavior is observed for s- and p-polarized infrared radiation, although the critical angle is the same for both.

The light that is internally reflected at the interface penetrates beyond it in the form of an evanescent wave. The amplitude of the evanescent wave falls exponentially with distance from the interface, such that the field strength at a distance z, denoted as $E(z)$, is given as

$$E(z) = E_0 \exp\left(\frac{-z}{d_p}\right) \tag{26.29}$$

The term d_p is the "depth of penetration", a parameter that depends upon the relative refractive indices of the two

media (n_1 and n_2), the wavelength (λ), and the angle of incidence (θ), and is effectively the distance at which the evanescent wave falls to $1/e$ of its value at the interface:

$$d_p = \frac{\lambda}{2\pi n_1 \left(\sin^2\theta - \left(\frac{n_2}{n_1}\right)^2\right)^{1/2}} \tag{26.30}$$

The evanescent wave can couple resonantly with vibrational dynamic dipole moments close to the interface. In such cases, energy is lost from the internally reflected wave, the process being referred to as *attenuated total internal reflection*. The magnitude of the attenuation is related to k for the material in contact; hence, a spectrum recorded using an ATR geometry is directly related to the true absorption spectrum (Mirabella, 2002). Figure 26.14(b) shows an illustration of the magnitude of the attenuation of total internal reflection for a semi-infinitely thick film of a

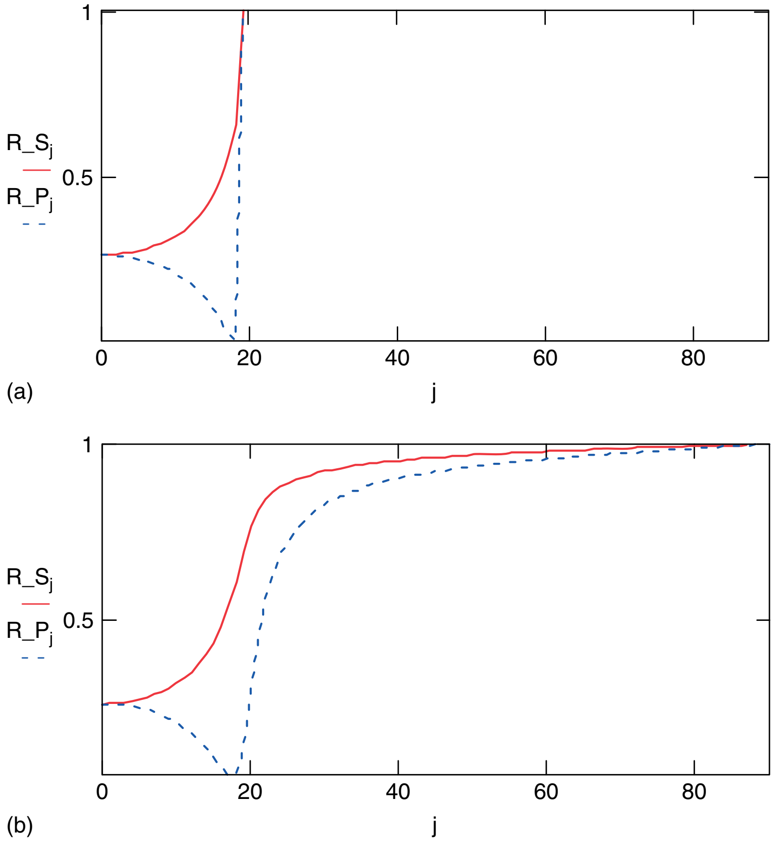

Fig. 26.14 (a) Modeled internal reflectivity of the interface between two transparent media (Ge, $n_1 = 4.0$ and vacuum, $n_2 = 1$) as a function of the angle of incidence for s- and p-polarization. (b) Modeled reflectance of the same interface with an infinitely thick layer of a weakly absorbing material replacing the vacuum ($n_2 = 1.2$, $k_2 = 0.03$).

moderately strong absorber ($n_2 = 1.2$, $k_2 = 0.03$) on a Ge internal reflection element (IRE). The magnitude of the attenuation is greatest close to the critical angle and decreases with increasing angle. There is also a difference in the attenuation of s- and p-polarized light. In practice, angles between 45 and 60° and unpolarized radiation are used, depending upon the nature of the materials to be studied and the application.

From the above equation, it can be clearly seen that there is a linear dependence of d_p upon the wavelength. At $2000\,\mathrm{cm}^{-1}$ for ZnSe (a common choice of material for ATR) at 60°, $d_p \approx 2\,\mu\mathrm{m}$ for example. The concomitant effect of the wavelength dependence of d_p on the evanescent field strength versus distance above the internally reflecting interface across the spectrum is that the intensity of absorption bands across the spectrum is therefore scaled linearly with λ. Most spectrometer software packages contain routines for correction of this phenomenon. However, care is needed while using these corrections, not least because spectrometer optics normally produce a 7–10° cone of incident angles at the IRE surface.

The advent of FTIR spectrometers has made a variety of experimental configurations viable for the collection of ATR infrared spectra, since both the sensitivity is higher and the optical configuration of accessories is not constrained by slits, as was the case in the original ATR-IR apparatus used by Harrick and Fahrenfort (Harrick, 1967) in the earliest practical demonstrations of the technique. The basis of all accessories is the IRE, and arrangements using prisms, trapezoids, parallelograms, cylinders, and hemispheres are or have been available in commercial devices. A primary choice is between multiple reflection and single reflection configurations, each having their own applications and advantages (Fitzpatrick and Reffner, 2002).

Multiple reflection ATR accessories for FTIR applications tend to use horizontal trapezoidal IREs. The effective path length in these IREs is hence a multiple of d_p for each reflection, with the number of reflections being readily calculated from the dimensions of the IRE. Given the limited range of the evanescent wave above the IRE surface, good contact is essential. High surface area horizontal IREs preclude the application of the high pressures necessary to ensure good contact between harder solids and the surface and so are of limited application to powders. However, these devices are very useful for solutions and soft solid materials. Typically, the IRE is mounted in a flat plate or trough. Light from the spectrometer compartment is coupled onto the beveled end of the IRE, undergoes multiple internal reflections, exits the end of the crystal, and is returned to the spectrometer light path. For high-index materials such as Ge, antireflection coatings on the input and output faces of the IRE are essential to increase optical throughput. Figure 26.15

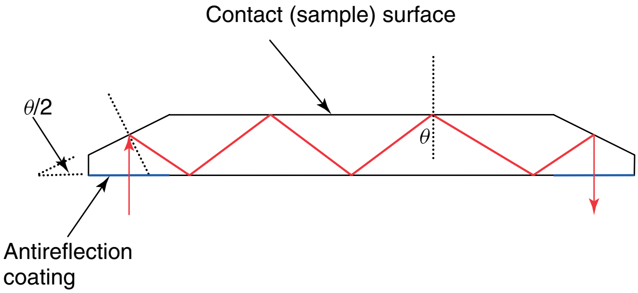

Fig. 26.15 Schematic of multiple internal reflection on a shaped prism (two reflections at the sampling interface). The angle of the beveled ends dictates the internal reflection angle θ. An antireflection coating is often used with high-index materials (e.g., Ge) to reduce reflection losses. In practice, IREs of this type are normally bonded into metal plates for location in optical carriages that translate the infrared beam to and from the sample compartment of a conventional FTIR spectrometer.

shows a horizontal ATR configuration in schematic. Flat plates and troughs are usually widely available, with choice depending upon application. In practice, these are normally removable for cleaning. Multiple internal reflection measurements of adsorption onto surfaces are also feasible, as demonstrated in the experiments of Chabal and coworkers, in which a polished and shaped silicon crystal was used as both a substrate for adsorption and an IRE (Chabal, 1986). Sensitivity well beyond that achievable for reflection–absorption or transmission measurements was achieved as a result of both the surface sensitivity and multiple reflections.

In recent years, single reflection ATR accessories have become more widely available. Figure 26.16 shows an example of the light path through a commercial sample-compartment-mounted single bounce ATR accessory. In this case, the IRE consists of a shaped ZnSe element with a thin diamond as the sample contact patch. Often such IREs also act as focusing elements, optimizing the amount of light directed onto the small diamond element (usually only a few millimeters in diameter). Light is coupled into and out of the IRE by plane mirrors, making a single internal reflection at the diamond/air interface. To improve sample contact between harder materials and the IRE, pressure can be applied with a clamp. ATR infrared spectra of liquids can also be obtained by placing small quantities of the liquid (or solution) analyte onto the diamond ATR, although it is often necessary to take steps to prevent evaporation from volatile media. ATR

accessories using composite (diamond-tipped) IREs are also widely used for in situ process monitoring, with the light from the spectrometer being directed to and from the IRE by fiber optics or light pipes. Single reflection accessories are also available with the ability to vary the internal reflection angle. These are useful for a number of purposes, including depth profiling and optical constant measurement. Figure 26.17 shows a schematic of a typical accessory, in which the infrared light from a spectrometer is coupled into and out of a prism IRE in such a way that the angle of incidence can be varied within certain limits.

ATR-based methods are now widely used as the method of choice for routine infrared analysis in a wide range of applications. However, the optics of the configuration also lend themselves to more esoteric applications. The effect of restricted spectroscopic penetration into an ambient medium using the ATR technique can be used effectively to study rates of diffusion in thin films deposited upon the surface of an IRE, as demonstrated by Pereira and Yarwood (1996). The rationale relies upon the diffusion process bringing material from an area beyond the sensitivity of the probe beam toward the IRE surface. As the material approaches the interface, it gives rise to spectral features whose intensity increases with time at a rate determined by the optical properties of the IRE/thin film and the rate of diffusion. The technique can be very sensitive when diffusion occurs upon an appropriate timescale for infrared measurements and has been applied to both polymers and condensed ice films. The rate of this diffusion can be calculated by assuming that the rate of diffusion is Fickian, in which case the absorbance versus time plot convolving spectral intensity with mass transfer will have the following form:

$$\frac{A(t)-A(0)}{A(\infty)-A(0)} = 1 - \frac{8}{\pi d_p\left(1-\exp\left[\frac{-2L}{d_p}\right]\right)} \sum_{n=0}^{\infty}\frac{1}{2n+1} \times \left[\frac{\exp\left[\frac{-2L}{d_p}\right]\left(\frac{2n+1}{2L}\pi\right)+(-1)^n\frac{2}{d_p}}{\left(\frac{2n+1}{2L}\pi\right)^2+\frac{4}{d_p^2}}\right]\exp\left[-\left(\frac{2n+1}{2L}\pi\right)^2 Dt\right] \tag{26.31}$$

where $A(t)$ is the absorbance at time t, $A(0)$ is the absorbance at $t = 0$, $A(\infty)$ is the saturation absorbance, d_p is the penetration depth (as defined in Eq. (26.30)), L is the thickness of the film, and D is the Fickian diffusion coefficient. Figure 26.18 shows a plot of the intensity of one of the characteristic features of ionized HCl diffusing through an ice film along with a fitted curve for a film thickness of 1.5 μm. A diffusion coefficient of $1.5 \times 10^{-15} \mathrm{m^2 s^{-1}}$ is obtained from this data (Horn and Sully, 1997).

26.2.5
Infrared Microspectroscopy

Infrared microspectroscopy (simply infrared microscopy in some references) relies upon the focusing of the infrared beam from an interferometer onto a microscopic sample and subsequent measurement of the infrared spectra of selected sections of the magnified image sampled from the focal plane of the collection optics. The optical considerations for infrared microspectroscopy are practically identical to those of optical microscopes. However, for infrared radiation with a wide range of constituent wavelengths, the use of reflection-based optical components is essential to minimize chromatic aberration. The smallest area from which individual nonoverlapping spectra can be obtained is of the order of the longest wavelength component of the radiation convolved with the numerical aperture of the condenser/objective elements, with about 25×25 μm^2 being a typical practical limit. Trade-offs between wavelength range, magnification, detector element size, and optical throughput must all be considered when selecting instrumentation. For single-point measurements, sample area (size and position) is selected from the magnified image in the focal plane of the objective element with an aperture. Since the amount of light reaching the detector through these various optical stages is relatively small (some 1–2 orders of magnitude less than conventional accessories), the use of high sensitivity, cooled MCT detectors is essential. Further details of the construction and design of conventional infrared microspectrocopy apparatus are given by Sommer (2002). Figure 26.19 shows a plain view of a commercial FTIR microscope, showing the complex light path needed for focusing, imaging, and magnification.

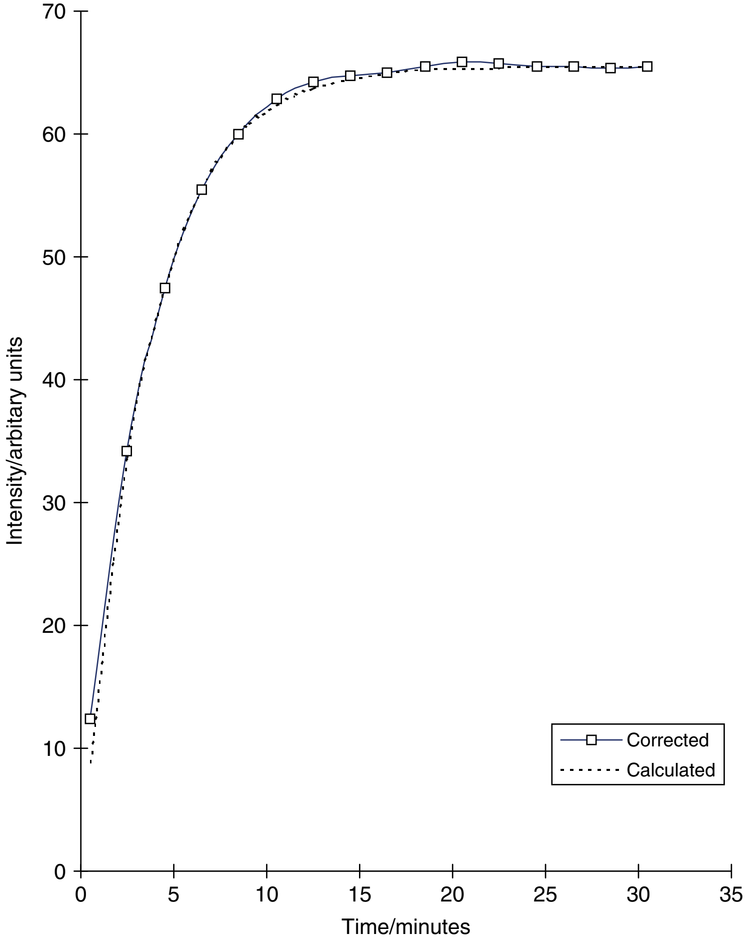

Fig. 26.18 Fickian diffusion of dissociated HCl through an ice film, measured by ATR. Taken from (Horn and Sully, 1997). The solid lines show measured integrated absorbance under the $\nu(H_3O^+)$ band, while the dotted line shows a fit using Eq. (26.31).

A variety of configurations are possible, including transmission, reflection, and ATR. Transmission measurements rely upon the production of films of sample that are sufficiently thin to keep absorbances below 1.0, which can be achieved by either microtoming samples or compression between optically transparent plates. When supported upon optically transparent substrates, corrections for focal length are needed because of refraction effects. Near-normal incidence reflection measurements are very similar in essence to transmission, differing only in the use of a reflective rather than optically transparent substrate and the simultaneous use of the objective as a condenser. For reflection at angles other than near normal, specialized objectives are needed to focus and collect

the infrared light. ATR objectives rely upon shaped IREs with the sampling area being determined by the size of the contact patch of the IRE. In practice, such objectives also need to incorporate an optical light path for the alignment and sample point selection. For further examples, see Humecki (1995) and references therein.

Major improvements in the sensitivity and usefulness of infrared microspectroscopy have arisen from two ways. The first is the use of synchrotron radiation sources for high-intensity infrared light. For example, an FTIR microscope recently developed at the Daresbury Laboratory in NW England utilizes an $8 \times 8\ \mu m^2$ spot from the synchrotron at high brightness. This has found application to a wide variety of microscopic samples, including prostate cancer cells with unique spectral features (Gazi *et al.*, 2007). Imaging of samples is also possible, with significant advantages over conventional sources where collection times are long due to the lower throughput.

Imaging the infrared image from the focal plane requires an array detector, and a number of such instruments are now widely available with focal plane array (FPA) detectors from 64 × 64 pixels upward. Step-scan interferometers are required for such applications in order to facilitate the recovery of interferograms from such an array. Technology is continuously improving in this field, with rapid increase in detector pixel number and density. The applications of such technology are widespread, especially in biological sciences, where the ability to extract chemical images from samples by integrating specific absorption bands provides unprecedented detail. In Figure 26.20, images of a eucalyptus leaf section from conventional microscopy, an imaged synchrotron microscope, and an FPA-based detector are shown (Heraud *et al.*, 2006). The authors compare the spatial resolution and the signal-to-noise ratio of the FPA imaging and synchrotron mapping methods. The quality of the images is roughly equal, with the main advantage being that the FPA images were obtained in about 2 minutes, compared to 8 hours using the synchrotron source, although the latter has superior signal-to-noise ratio and potentially better spatial resolution. The major features of the internal structures of the leaf are clearly seen from the integrated amide I band.

26.2.6
Extinction Methods from Particles

When infrared light is incident upon particles with diameters similar to that of the wavelength of the light, scattering occurs. This results in an extinction spectrum that is the sum of a scattering contribution that scales with wavenumber and particle radius and an absorption contribution due to vibrational resonances, which is dependent on concentration, absorption coefficient, and path length of the absorbing species. Typically, Mie theory can be used to relate the observed infrared spectrum to aerosol size and concentration. A number of assumptions must be made for simplification: (i) that scattering is elastic (frequency of scattered light is equal to that of incident light); (ii) only single-scattering occurs (i.e., the particles do not affect each other); (iii) the complex refractive index completely describes the optical properties of the particles; and (iv) the number of particles is large with random separations such that there is no systematic phase relation between waves scattered by individual particles (Bohren and Huffman, 1983). The intensity of light, I, passing through an aerosol is given as

$$\frac{I}{I_o} = e^{(-b_{\text{ext}}\,z)} \tag{26.32}$$

where I_0 is the incident intensity, z is the path length, and b_{ext} is the extinction coefficient. Typical treatments are expressed in terms of τ_{ext}, the light removed from the incident beam by the combined effect of scattering and absorption:

$$\tau_{\text{ext}} = \log_{10}\left(\frac{T_o}{T}\right) = \log_{10}\left(\frac{I_o}{I}\right) = \frac{b_{\text{ext}}\text{z}}{2.303} \tag{26.33}$$

For a distribution of particles with a range of diameters, it can be shown that

$$\tau_{\text{ext}} = \frac{1}{4}\frac{\pi {d_p}^2}{2.303}N(d_p)\text{Q}_{\text{ext}}(d_p)\text{z} \tag{26.34}$$

where d_p is particle diameter, $N(d_p)$ is the size-dependent number concentration, and $Q_{ext}(d_p)$ is the size-dependent extinction efficiency. Light extinction by small particles within the infrared light path has scattering and absorption contributions such that

$$Q_{ext} = Q_{sca} + Q_{abs} \tag{26.35}$$

Mie theory gives a basis for the calculation of the scattering and

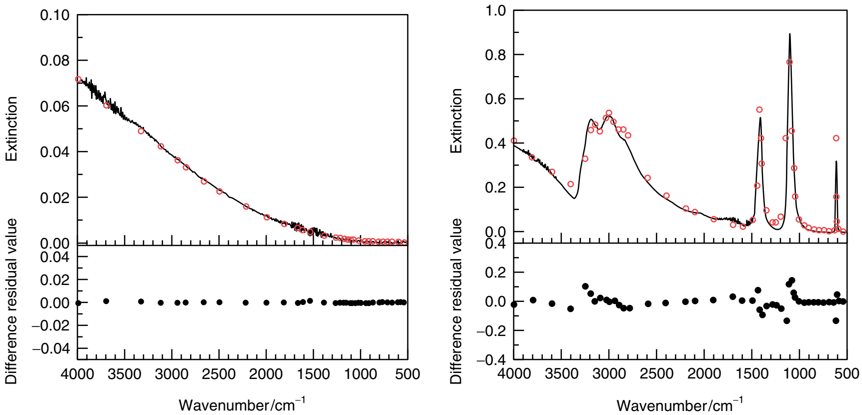

Fig. 26.21 Infrared extinction spectra from aerosols. (a) NaCl aerosols with average diameter 2.1 μm and number density 3.2×10^5 particles cm^{-3}. (b) $(NH_4)_2SO_4$ aerosols with 2.0 μm and $N = 1.1 \times 10^6$ particles cm^{-3}. In each case, the upper panels shown the FTIR extinction spectra (solid lines) and the best fit results based on Mie scattering calculations (circles). absorption of light by any spherical particle (with diameter d_p) as a function of the size distribution, number density of the aerosol particles, and the complex refractive index. Q_{ext} and Q_{sca} are usually determined iteratively. In practice, for materials with known wavelength-dependent complex refractive index, a test spectrum can be generated using these extinction coefficients based on an input size distribution and number density, with these parameters iteratively fitted to achieve a match to the real spectrum (Zasetsky *et al.*, 2007). Figure 26.21 shows a fit for two examples using published optical constants. For pure sodium chloride aerosols, there is no absorption component and the spectrum is entirely due to scattering. For ammonium sulphate particles, both scattering and absorption are present. The lower panels show the residual from the calculated versus measured spectra (Najera *et al.*, 2009).

26.3
Interpretation of Infrared Spectra

26.3.1
Empirical Interpretation from Group Frequencies

The interpretation and analysis of infrared spectra draws upon a number of tools, some empirical and some more rigorous. Databases of library spectra have been available for many years (from Sadtler, Aldrich, Hummel among others), and algorithms for the comparison of spectra with those contained in reference libraries for the identification of compounds are constantly evolving. However, to use infrared spectroscopy as a black box method in such a manner would be to miss a substantial part of the richness of molecular information and complexity contained within an infrared spectrum. Therefore, this section concentrates on the methodology of first principles interpretation of infrared spectra using group frequencies and correlation tables. The interpretation of infrared spectra requires both a systematic approach to the assignment of functional group modes and an understanding of the nature of the effect of the intramolecular structure on the precise position of absorption bands. In particular, it is often considered essential to make correlations between the appearances of different types of group modes.

As discussed in the preceding sections, although many individual displacements make up a vibrational mode, the combinations which dominate a given normal mode tend to be of similar frequencies. Adjacent parts of a molecule often move independently of the rest of the molecule when masses are very different or when force constants are very different. A normal mode may then be mostly made up from the displacement of the atoms of a single functional group, with a characteristic absorption frequency almost regardless of the rest of the molecules. Normal modes tend to be dominated by a specific type of motion. For each individual atomic displacement in a polyatomic molecule, two possibilities exist: displacement along the bond direction (stretch) and displacement perpendicular to the bond direction (deformation). A variety of nomenclature exists, but in general functional group modes tend to be labeled ν if they involve mainly stretching, δ if they mainly involve bond bending, ρ if they mainly involve rocking, and τ if they involve twisting. It is common to label symmetric and antisymmetric vibrations with subscripts, for example, $\nu_s(H_2O)$ for the symmetric OH stretching mode of water.

The most useful functional group modes for direct assignment tend to be those which occur in regions of the spectra where there are few other resonances. However, functional groups in spectrally congested regions can frequently be identified when their presence is correlated with other types of vibration of the same group. This might occur in several ways, the simplest being when there are either two functional group modes within a single functionality or there are two types of vibration (e.g., stretching and deformation) of the same functionality.

Aldehydes (R$-$CHO) provide an excellent example of the former. The stretching mode of the aldehydic C$-$H bond, written as ν (C$-$H), typically occurs between 2900 and 2700 cm^{-1} and is usually quite weak, although often clearly distinguishable because the region of the spectrum in which it occurs is normally uncluttered by other resonances. The related aldehydic carbonyl stretching mode, labeled as ν (C=O), typically occurs between 1740 and 1720 cm^{-1} and is normally very strong. These features do not vary much between different aldehydes. Consequently, the presence of both together is a clear marker for the presence of an aldehydic functionality, regardless of the composition of the rest of the molecule. Furthermore, as discussed later, the band position of an aldehydic C=O is often sufficiently different from that of other carbonyl species.

An example of the latter is as follows: the presence of two types of vibration of the same set of atoms occurs widely in organic molecules and in biological materials. The stretching modes of methyl ($-CH_3$) and methylene ($-CH_2-$) groups can be observed in the 3000–2800 cm^{-1} range, a relatively uncluttered region. The corresponding deformation modes occur in the 1500–1350 cm^{-1} range, which is usually highly congested in all but the simplest molecules. Specifically, methylene groups in long alkane chains show symmetric $\nu_s(CH_2)$ and antisymmetric $\nu_{as}(CH_2)$ stretching modes at approximately 2860 and 2930 cm^{-1} and a deformation mode $\delta(CH_2)$ at 1470 cm^{-1}. The former are often readily identifiable: their presence allows confidence in the assignment of a spectral feature around 1470 cm^{-1} to $\delta(CH_2)$. Similarly for a methyl group, the symmetric $\nu_s(CH_3)$ and antisymmetric $\nu_{as}(CH_3)$ stretches occur at approximately 2870 and 2970 cm^{-1}, accompanied by symmetric $\delta_s(CH_3)$ and antisymmetric $\delta_{as}(CH_3)$ deformations at approximately 1375 and 1460 cm^{-1}. At a slightly higher level of complexity, bands of this type also show predictable patterns of relative band intensities and characteristic band positions.

The variation of group frequencies from one molecule to another provides a further challenge to the spectroscopist. Some group modes are relatively immobile, regardless of their molecular environment (e.g., methyl and methylene stretching modes). Others, particularly those derived from functionalities that couple strongly through either inter- or intramolecular interactions, exhibit substantial ranges.

In the latter case, shifts in position (and intensity) arise because of chemical and physical interactions. Double bonds can conjugate, resulting in reduced electron density within a specific region of the molecule, thereby reducing the force constant. For example, in isolated C=C and C=O double bonds, absorptions are observed from $\nu(C{=}C)$ at approximately 1650 cm^{-1} and from $\nu(C{=}O)$ at ca. 1720 cm^{-1}. In conjugation, for example, in C=C−C=O, the $\nu(C{=}C)$ absorption shifts to approximately 1600 cm^{-1} and the $\nu(C{=}O)$ absorption shifts to approximately 1675 cm^{-1}. Intermolecular forces also affect vibrational frequencies, again through perturbation of the electron density within a chemical bond (or set of bonds). For example, H-bonding lengthens and weakens O−H bonds such that $\nu(O{-}H)$ values vary widely (as does the band width). Interactions such as this tend to increase the frequency of deformation modes. Solution effects may also alter frequencies. Being highly polarized, carbonyl compounds interact with solvents, H-bonding with water and alcohols, and so on, with a resultant small shift (usually to lower wavenumber) of the band position.

Carbonyl compounds provide an excellent example of the effects of intramolecular phenomena such as induction (donation or loss of electron density from substituents), angle strain, and resonance upon bond strengths and therefore the positions of absorption bands. Inductive effects due to electron-withdrawing (−I) groups attached to the C atom compete with the $C^+{-}O^-$ resonance form and increase bond strength; hence, $\nu(C{=}O)$ increases, for example, $\nu(>C{=}O)$ in aldehydes $\approx$ 1720 cm^{-1} while $\nu(-COCl) \approx$ 1800 cm^{-1}. Electron-donating (+I) groups attached to the C atom stabilize the $C^+{-}O^-$ resonance form and reduce bond strength; hence, $\nu(C{=}O)$ decreases. Strain effects, where the angle formed between the two substituents is forced away from the preferred 120°, increase $\nu(C{=}O)$. This is particularly prevalent in cyclic systems. Mesomeric effects are those where one or some other forms of the resonance are stabilized by substituents or through interaction with other species. H-bonding may preferentially stabilize one of the mesomeric forms, for example ($C{=}O^- \ldots H{-}X \leftrightarrow C^+{-}O^- \ldots$

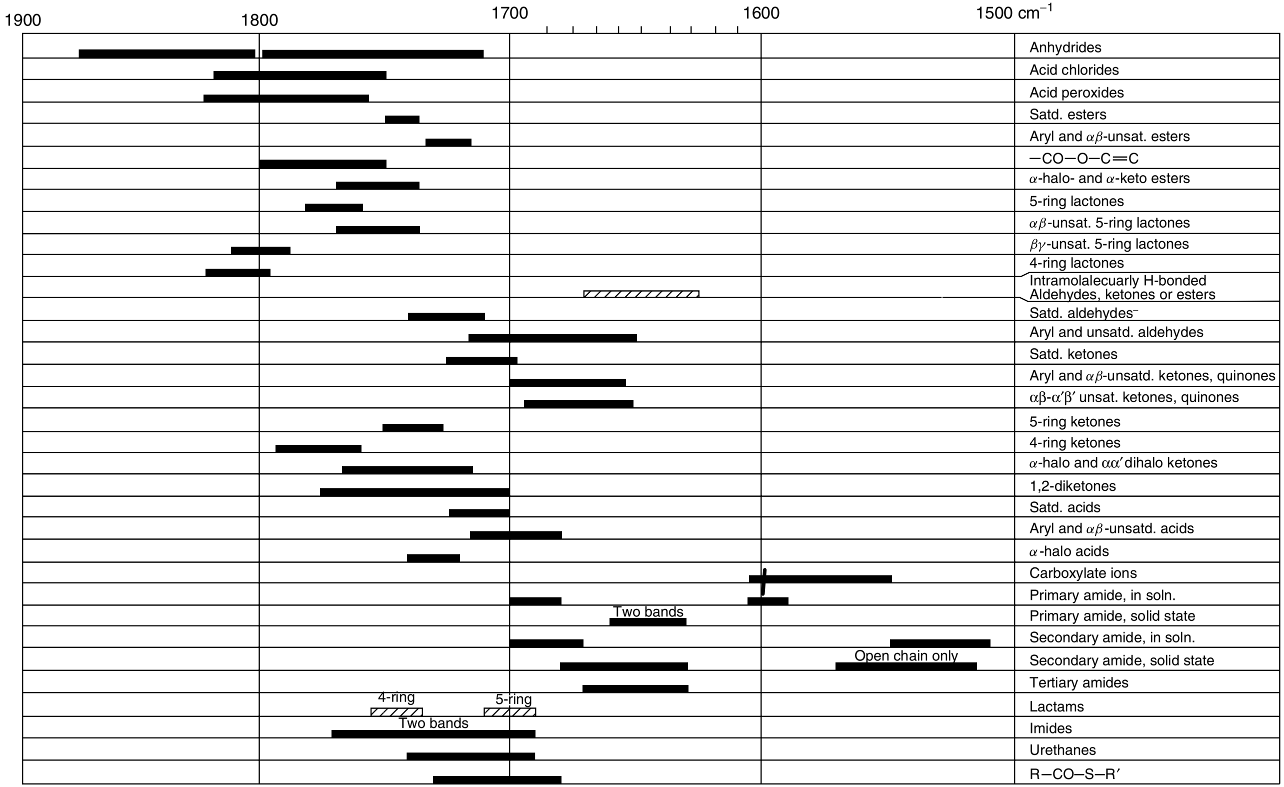

Fig. 26.22 Group frequency correlation table for the carbonyl region. Taken from Williams and Fleming (1995).

H−X), which again lowers the ν(C=O) frequency.

The above-mentioned factors are described in much greater depth in a range of textbooks (e.g., Williams and Fleming, 1995; Socrates, 2004). The information is often summarized in *group frequency correlation tables* such as that shown in Figure 26.22. A systematic approach is required for confidence in assignment. It is often easier to make correlations between the appearance of group modes if the spectrum is considered in a number of well-defined regions. Table 26.2 summarizes the regions in which the main functional group modes occur.

In larger molecules, a substantial proportion of the absorption bands is not easily assigned to vibrational modes of a specific functional group. These absorptions mainly occur below 1500 cm^{-1}, resulting in a congested spectral region. Bands that can sometimes be identified in this region include the C−C skeletal modes of organic molecules. The absorption pattern of molecules in this region is normally strongly characteristic, leading to its use as a fingerprint. However, there are functional group modes that occur in this region, some of which are readily identifiable by virtue of their intensity.

Of particular interest are the absorption bands that arise from the deformation modes of aromatic C−H moieties, especially the out-of-plane ring δ(CH) modes. These show large intensity as a result of both high amplitude of vibration of the H atoms and the large dynamic dipole that arises from the aromatic electron density. Characteristic patterns are observed for the various substitution patterns around aromatic rings. Typically, they lie between 985 and 750 cm^{-1}, with some modes being quite intense. Although they are generally rather insensitive to the nature of the substituent, the pattern of modes observed in the spectrum usually depends upon the number of adjacent hydrogen atoms on the ring (i.e., the number of substituents and where they are with respect to one

Tab. 26.2 Spectral regions in which typical functional group modes can be identified.

Spectral Region (cm^{-1})	**Type**	**Comments/examples**
4000–2300	Hydrogenic stretching modes	H lightest atom, no X=H bonds
2400–1900	Triple bonds and cumulated double bonds	Nitriles, ν(CN) ≈ 2250 cm^{-1} Allenes, ν(−C=C=CH$_2$) ≈ 1940 cm^{-1}
2000–1400 cm^{-1}	Double bonds	Cyano, ν(>C=N-)≈ 1680 cm^{-1} Benzene rings ≈ 1600, 1580, 1500, 1470 cm^{-1} Carbonyls, ν(>C=O) ≈ 1900–1500 cm^{-1}
1600–1000 cm^{-1}	Deformation (bending) modes to hydrogen	Methylene, δ(CH$_2$) ≈ 1450–1480 cm^{-1} Methyl, δ(CH$_3$) ≈ 1450, 1380 cm^{-1} amine, δ(NH$_2$) ≈ 1600 cm^{-1}
1500–400 cm^{-1}	Heavier atom stretches or light atom deformations	Aromatic out of plane ≈ 985–750 cm^{-1} C−O single bonds ≈ 1300–1050 cm^{-1}

Tab. 26.3 Vibrational frequencies for the δCH(op) in phase wagging mode.

Substitution	Wavenumber (cm^{-1})	Adjacent H
Mono	766–736	5 adjacent H[a]
o-di	758–744	4 adjacent H
m-di	791–773	3 adjacent H[a]
p-di	830–804	2 adjacent H

[a] Monosubstituted and *m*-disubstituted benzenes usually show the out-of-plane sextant ring bending mode at approximately 700 cm^{-1} as well.

another). This behavior is summarized in Table 26.3.

In summary, the interpretation of infrared spectra of single component species relies strongly upon the expertise of the analyst. However, once assigned, variations in band position, intensity, linewidth, or band shape from known reference materials in well-defined states convey a large quantity of subtle information.

28.1
Introduction

Molecular structures are essential to understand the function and mechanism of molecules. The use of nuclear magnetic resonance (NMR) spectroscopy to determine the structure of biomolecules in solution has the advantage of reproducing the environment in which these molecules are naturally found.

The aim of this chapter is to provide an introduction to how NMR spectroscopy is applied to structural studies of biomolecules, following the steps described below. It is not the aim to provide an extensive review of structure determination of biological macromolecules using solution NMR, and although NMR spectroscopy can be successfully used to study the dynamics of molecules and molecular interactions (see, for example, Palmer, 2001; Kay, 2005; Latham *et al.*, 2005), these techniques are beyond the scope of this introduction.

Biological macromolecules have a number of characteristics in common, and they present a number of common challenges. The process of structure determination by NMR usually starts with the assignment of chemical shift values to the relevant nuclei in the molecule, followed by the determination of a number of structural restraints. Specific pulse sequences are available for each of those steps. The structural restraints are then used for molecular simulations, using simulated annealing techniques and molecular dynamics. Each type of structural restraint is added to the molecular energy representation as a separate pseudo-energy term, and the simulation explores the conformational space to find the minimal energy structures.

As a solution technique, NMR-determined structures reflect the heterogeneity of conformations presented by biomolecules in solution. Specific challenges in this aspect are intrinsically disordered proteins (see Dyson and Wright, 2005, for a review), which do not have a well-defined tertiary structure in their native state in the absence of their binding partner, and larger oligosaccharides and polysaccharides, that tend to be highly flexible and dynamic (Martin-Pastor and Allen Bush, 1999). In these cases, the structures determined reflect a distribution of conformations, rather than a single structure (Yi *et al.*, 2004; Lindorff-Larsen *et al.*, 2004; Osterhout *et al.*, 1989).

When compared to small organic molecules, the acquisition of NMR spectra of biological macromolecules

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

presents a number of challenges. Experiments are generally performed in water, making good suppression of the solvent signal essential. In addition, the number of signals from the different ^{1}H nuclei in a biological macromolecule inevitably leads to overlapping in the one-dimensional spectrum, requiring high-field spectrometers and multidimensional spectra to resolve the individual resonances.

28.2
Spectra Acquisition

28.2.1
Nuclei

The most common atoms in biological macromolecules are carbon, hydrogen, nitrogen, and oxygen. The magnetic properties of their stable isotopes are summarized in Table 28.1.

The most abundant hydrogen isotope, ^{1}H, has the highest sensitivity, and is the most widely used nucleus for NMR. The most abundant carbon isotope, ^{12}C, has no nuclear spin, whereas the most abundant nitrogen isotope, ^{14}N, has a spin number of 1 and strong quadrupolar moment, leading to fast relaxation. Less abundant isotopes of both, however, have spin number ½. ^{13}C is present as about 1% of the total carbon, and natural abundance spectra are routinely acquired for small molecules. For larger molecules such as proteins, the weak signal would make the acquisition of multidimensional spectra overly long, and ^{13}C labeling of proteins is a standard technique. The same is true of ^{15}N, even less abundant naturally. The only stable magnetically active oxygen isotope is ^{17}O, with a spin number of 5/2, and it is not normally used for solution NMR of biomolecules. ^{31}P is naturally present in all nucleic acids and in some carbohydrates and proteins, and is often used as an additional source of information. Although other nuclei can be used to study biomolecules, structural determination is usually performed using

Tab. 28.1 Magnetic properties of the stable isotopes of biologically abundant atoms. γ is the gyromagnetic ratio.

Isotope	Spin	Natural abundance (%)	γ (10^7 rad T^{-1} s^{-1})	Sensitivity		Frequency at 11.7 T
				Relative to proton	At natural abundance	
^{1}H	½	99.985	26.75	1.00	1.00	500.000
^{2}H	1	0.015	4.11	9.65×10^{-2}	1.45×10^{-6}	76.753
^{12}C	0	98.89				
^{13}C	½	1.108	6.73	1.59×10^{-2}	1.76×10^{-4}	125.721
^{14}N	1	99.63	1.93	1.01×10^{-3}	1.01×10^{-3}	36.118
^{15}N	½	0.366	−2.71	1.04×10^{-3}	3.85×10^{-6}	50.664
^{16}O	0	99.75				
^{17}O	5/2	0.037	−3.63	2.91×10^{-2}	1.08×10^{-5}	67.784
^{18}O	0	0.205				
^{31}P	½	100	10.83	6.63×10^{-2}	6.63×10^{-2}	202.405

multidimensional ^1H, ^{15}N, and ^{13}C spectra. ^{15}N and ^{13}C are indirectly detected, with the magnetization being transferred back to protons for ^1H direct detection. These experiments require triple-resonance probes, capable of pulsing and decoupling ^{13}C and ^{15}N, sometimes simultaneously, while pulsing and detecting ^1H (Cavanagh *et al.*, 1996).

28.2.2
Sample Preparation

Solution NMR of biological macromolecules is usually performed in 90% H_2O/10% D_2O, with the buffer and salt concentrations depending on the requirements for stability of the molecules being studied. Where possible, sample pH should be kept below 7.5 to slow down the exchange rate of the backbone amide protons with the solvent, which leads to loss of signal, and salt concentration should be kept low and buffers of low conductivity should be chosen, as higher buffer conductivity will decrease the signal-to-noise ratio (Kelly *et al.*, 2002).

The large number of atoms in biological macromolecules results in heavy overlapping of resonances in the ^1H spectra, requiring uniform labeling with ^{15}N and/or ^{13}C for resolution of the overlapped peaks in multidimensional spectra. For larger molecules, additional uniform labeling with ^2H is required to decrease transverse relaxation rates (Grzesiek *et al.*, 1993). Deuterated protein samples are usually purified in ^1H_2O-based buffers, resulting in substitution of the deuterium bound to the main-chain nitrogen with protons.

The requirement for labeled protein means that protein samples for NMR spectroscopy are normally obtained by recombinant expression in an organism that can be grown in a medium of controlled composition, to which the only source of nitrogen or carbon can be added with defined isotopic composition. Most commonly, proteins are expressed in *Escherichia coli* grown in minimal media, having glucose as the only source of carbon, and NH_4Cl or $(NH_4)_2SO_4$ as the only source of nitrogen. Uniformly labeled ^{13}C-glucose and $^{15}NH_4Cl$ and $(^{15}NH_4)_2SO_4$ are available commercially. For deuterated proteins, the minimal media can be prepared with D_2O instead of ^1H_2O, and conditioning protocols may be required for good bacterial growth and protein expression (Li, Corson and Sykes, 2002). Rich media containing ^{15}N, ^{13}C, and ^2H are also commercially available, and generally produce much better bacterial growth than minimal media, but are significantly more expensive. When a protein cannot be successfully expressed in bacterial cells, eukaryotic expression systems can be used, such as the yeast *Pichia pastoris* (Morgan, Kragt and Feeney, 2000) or insect cells (Brüggert *et al.*, 2003). More recently, cell-free expression systems have been developed (Vinarov *et al.*, 2004; Torizawa *et al.*, 2004).

For larger proteins or specific experimental requirements, alternative labeling schemes can be required, instead of uniform labeling. Examples include different schemes for selective protonation of methyl groups in amino acid side chains, while the rest of the protein is deuterated (Gardner and Kay, 1998).

For nucleic acids, it is also necessary to obtain pure ^{13}C, ^{15}N-labeled samples in milligram amounts. Most RNA samples are produced *in vitro* by transcription of a DNA template by T7 polymerase (Milligan *et al.*, 1987; reviewed by Fürtig *et al.*, 2003; Flinders and Dieckmann, 2006; Dayie, 2008). Template DNA often includes the sequence for a self-cleaving ribozyme, which will aid in purification and help in overcoming the limitations of T7 polymerase. Uniform labeling is commonly performed by using labeled NTPs as the substrate for the T7 polymerase reaction, but for large RNAs (over 20–30 nucleotides), specific labeling approaches may be required (reviewed in Latham *et al.*, 2005; see Nelissen *et al.*, 2008, for a recent example). Chemical synthesis is an alternative for small RNAs, and has been reviewed by Lagoja and Herdewijn (2002). DNA samples can be obtained by purifying a suitable plasmid containing multiple copies of the desired oligonucleotide from a bacterial culture grown in ^{15}N, ^{13}C-labeled medium, or from a polymerase chain reaction (PCR)-based approach (Louis *et al.*, 1998; René *et al.*, 2006).

Labeled carbohydrate samples for NMR studies can be even more difficult to produce, because the residue sequence in glycans often depends on species-specific synthetic pathways. NMR of small oligosaccharides can be performed on natural abundance ^{13}C, and is often used in combination with other techniques. Glycans from species that can be grown in labeled medium, such as bacteria and fungi, can be normally purified. A review of successful examples of uniform labeling in carbohydrates was done by Duus, Gotfredsen and Bock (2000), but a labeling method generally applicable to carbohydrates is not yet available. Alternative approaches for partial labeling include the enzyme-catalyzed exchange of acetyl groups with ^{13}C-enriched acetic anhydride (Yu and Prestegard, 2006).

28.2.3
Pulse Sequences and Processing Strategies

While specific pulse sequences used to determine chemical shift assignments or structural restraints are mentioned in the following sections, a few general methods can be applied to a range of pulse sequences to make them more effective or faster. Pulse sequences for biological experiments also need to contain solvent suppression pulses, because the experiments are normally performed in 90% H_2O/10% D_2O. Different water suppression techniques can be used in different pulse sequences, and depending on the characteristic of the sample. When observing protons that can easily exchange with the solvent, in nucleic acids for instance, it is important to avoid methods involving presaturation of water (more commonly used in protein studies), and utilize pulse sequences that use jump-and-return techniques (Hore, 1983; Sklenár and Bax, 1987) or the WATERGATE method (Piotto, Saudek and Sklenár, 1992).

Original multidimensional pulse sequences relied on phase cycling to eliminate unwanted signals and minimize artifacts. By changing the phase of specific pulses and the receiver, unwanted signals can be cancelled. This requires repeating the experiment with the different phase combinations, and can result in a number of repetitions much larger than needed for a good signal-to-noise ratio. In probes with pulsed-field gradient capabilities, part of the phase cycling can be replaced by the use of gradient pulses. Field gradient pulses are pulses that create a varying field along the axis of the sample, resulting in defocusing of the magnetization, which can be recovered by applying another gradient pulse, of opposite signal. If those pulses are applied at the right point in the pulse sequence, only the desired signals will be selected. Phase cycling is then used to minimize artifacts, with a smaller number of repetitions.

For larger biomolecules, one of the limiting factors is the fast transverse relaxation, which increases with the rotational correlation time. Fast transverse relaxation broadens the spectral lines, and leads to loss of signal due to relaxation during the pulse sequence. However, the four lines in an undecoupled peak quartet in a heteronuclear correlation spectrum do not relax at the same rate. Transverse relaxation optimized spectroscopy (TROSY) selects the multiplet component with slower relaxation rate, eliminating the other lines (Pervushin *et al.*, 1997; Wider and Wüthrich, 1999). Although only part of the signal is being recovered, the spectral lines show better resolution and signal-to-noise than the comparison standard PEP-HSQC (heteronuclear single quantum coherence) spectrum used for heteronuclear correlation spectroscopy, and this effect is intensified for large molecules. The TROSY effect is field-dependent, being more pronounced at higher fields. It is normally used in conjunction with deuterated samples, which also help to increase the transverse relaxation times. TROSY elements have been incorporated in a number of multidimensional pulse sequences, for use with large molecules (Wider and Wüthrich, 1999).

While TROSY and other techniques aim to increase sensitivity and extend NMR experiments to large and otherwise troublesome proteins, there are various techniques to decrease experimental time when signal is abundant. They include SOFAST-HMQC experiments (Schanda, Kupce and Brutscher, 2005), Hadamard NMR (Kupce, Nishida and Freeman, 2003; Brutscher, 2004), single-scan NMR (Frydman, Scherf and Lupulescu, 2002), projection NMR (Szyperski *et al.*, 1993; Brutscher *et al.*, 1994; Kupce and Freeman, 2004), hyperdimensional NMR (Kim and Szyperski, 2003; Kupce and Freeman, 2008), nonlinear data recording and processing (Mandelshtam, 2000; Hoch and Stern, 2001; Rovnyak *et al.*, 2004), and covariance spectroscopy (Brüschweiler and Zhang, 2004). A number of these techniques were reviewed a few years ago (Freeman and Kupce, 2003).

28.3
Chemical Shift Assignment

There is no single unified method for obtaining chemical shift assignments for polypeptides, polynucleotides, and polysaccharides. Proteins, nucleic acids, and carbohydrates have different characteristics, and the methods for chemical shift assignment differ, even though some of the pulse sequences used are the same. Most of the pulse sequences required for the assignment of biomolecules are provided in the standard installation of modern high-field NMR spectrometers. Chemical shift assignments of biological macromolecules are deposited in the Biological Magnetic Resonance Bank (BMRB) (Ulrich *et al.*, 2008), which is also a useful source for other resonance data, such as average chemical shift values for each amino acid type. Once the chemical shift values seen in the spectra have been assigned to specific nuclei in the biomolecule, structural restraints can be defined for different atoms in the molecule.

28.3.1
Chemical Shift Assignment in Proteins

There are two stages in assigning chemical shift values to individual nuclei in proteins. First, the backbone is assigned using the sequential assignment method, created by Kurt Wütrich (Nobel prize winner in Chemistry in 2002) and coworkers (Wagner and Wüthrich, 1982; Wüthrich, 1986; reviewed in Ferentz and Wagner, 2000; Kanelis, Forman-Kay and Kay, 2002). The side chains of each residue are assigned in a second stage. Modern experiments used for chemical shift assignment are mostly ^{15}N-edited three-dimensional spectra, and are intimately connected to the labeling scheme used for the sample. For most proteins, ^{1}H, ^{13}C, and ^{15}N information is required, from a sample double-labeled with ^{13}C and ^{15}N. For large proteins, it is often not possible to perform three-dimensional NMR experiments in a fully protonated protein, due to the short transversal relaxation time (T_2), which leads to very fast signal decay and line broadening. Main-chain amide protons are usually back-exchanged into deuterated proteins, and specific suites of triple-resonance experiments are the basis for chemical shift assignment (Gardner and Kay, 1998).

Figure 28.1 shows schemes of the magnetization transfer in the most commonly used pulse sequences for backbone sequential assignment in proteins. Sequential assignment starts with a reference spectrum, a 2D {^{1}H, ^{15}N}-HSQC in which a peak corresponds to each main-chain amide, or a 3D HNCO (Kay *et al.*, 1990; Grzesiek and Bax, 1992b), which correlates the proton and nitrogen of a main-chain amide with the carbonyl carbon from the previous amino acid residue. An ideal HSQC or HNCO spectrum will have a peak for every residue in the protein, but N-terminal residues often cannot be seen due to fast exchange with water protons, and loss of magnetization during the water suppression scheme. The faster exchange in this region is caused by the positive charge in the amino terminus of the protein. Conversely, C-terminal residues often give much stronger signals than the rest of the protein. Conformational exchange can also lead to peak broadening beyond detection, and peaks missing from the reference spectrum. Conformational exchange in the protein can also lead to the loss of peaks for some residues.

The basic experiments for backbone assignment of a medium-sized protein are HNCACB (Wittekind and Mueller, 1993) and CBCA(CO)NH (Muhandiram and Kay, 1994; Grzesiek and Bax, 1992a), HNCO and HN(CA)CO (Clubb, Thanabal and Wagner, 1992). HNCACB correlates the amide proton and nitrogen of each residue with the α- and β-carbons of the same amino acid residue more strongly, and with the α- and β-carbons of the previous residue more weakly, while CBCA(CO)NH correlates the amide proton and nitrogen of each residue with the α- and β-carbons of the previous residue only. Sequential assignment is done by matching the weaker peaks in each strip of the HNCACB spectrum with the peaks in a strip of the CBCA(CO)NH spectrum, forming a "chain" of spin systems. Residues with characteristic chemical shift values, such as serine, threonine, glycine, and alanine, help anchor this chain in relation to the amino acid sequence in the protein.

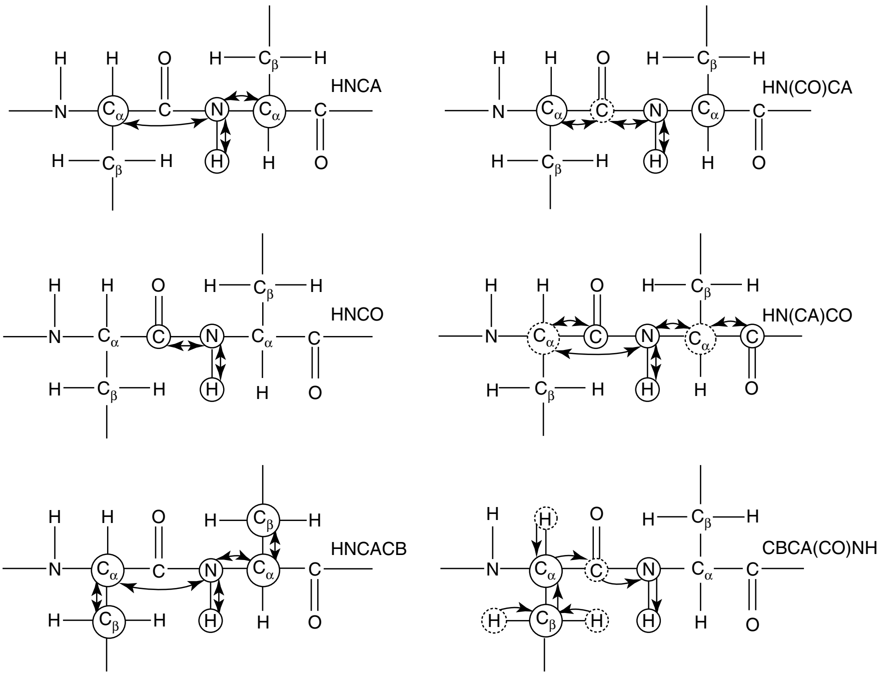

Fig. 28.1 Magnetization transfer steps in pulse sequences used for protein sequential assignment. Nuclei that are not correlated in the final spectra are represented in dashed circles, nuclei correlated in the final spectra are inside solid circles, and magnetization transfer is represented by arrows. With the exception of CBCA(CO)NH, the magnetization in all pulse sequences in the figure starts from the amide proton is transferred to the heteronuclei and back to the amide proton for data acquisition. In CBCA(CO)NH, the magnetization starts in the protons bound to C_β and C_α.

An example of sequential strips in HNCACB and CBCA(CO)NH spectra can be seen in Figure 28.2.

The CBCA(CO)NH experiment is not applicable to deuterated proteins, because it starts by transferring magnetization from the hydrogen atoms bound to the β-carbon (Figure 28.1). When the ^1H is replaced with deuterium, this pulse sequence is not applicable anymore. Instead, the HN(CO)CACB pulse sequence can be used. In large proteins (over 30 kDa), however, the signal that can be obtained with HNCACB and HN(CO)CACB is often too weak, and the combination of HNCA (Grzesiek and Bax, 1992b; Stonehouse *et al.*, 1995) and HN(CO)CA (Bax and Ikura, 1991) experiments can used. Only correlating the α-carbon with the amide, these experiments have better signal-to-noise ratios than HNCACB and HN(CO)CACB under the same conditions. The disadvantage, however, is that they contain less information. Other labeling schemes and pulse sequences have been developed to extend chemical shift assignment procedures to even larger proteins, up to 82 kDa (Tugarinov, Hwang and Kay, 2004).

A number of semiautomated and automated backbone assignment programs

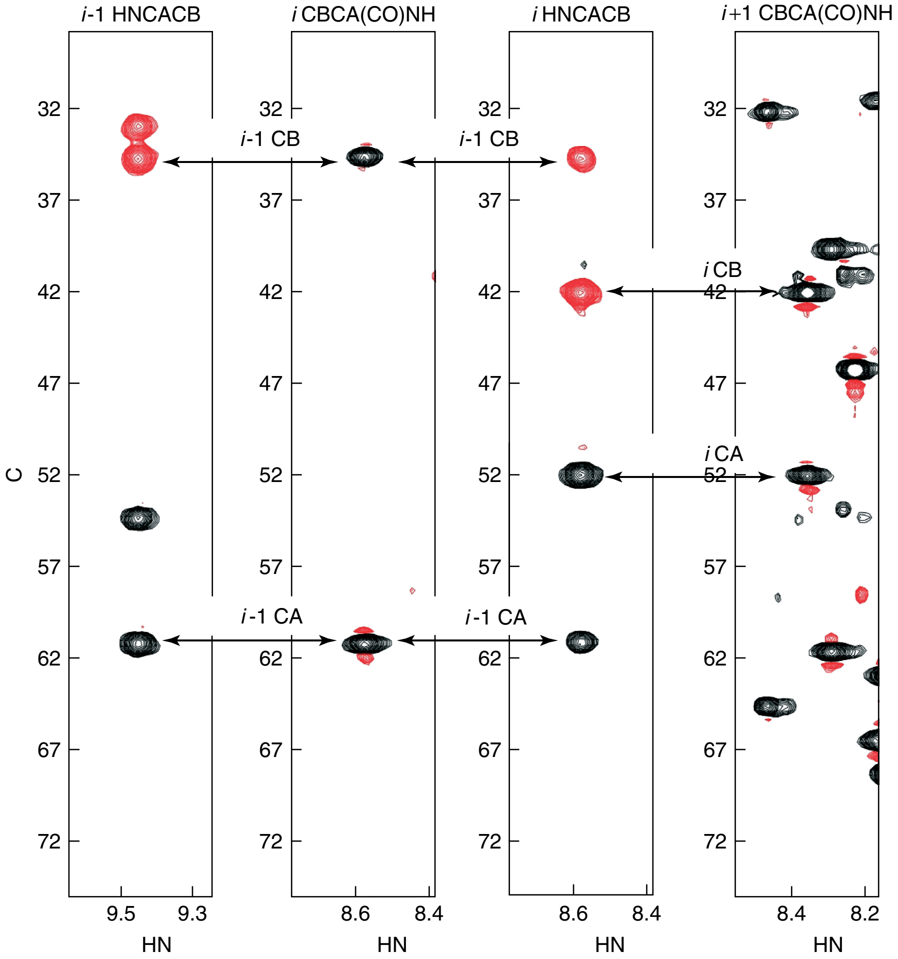

Fig. 28.2 Strips from three-dimensional HNCACB and CBCA(CO)NH spectra for sequential assignment, showing the connectivities between three sequential residues, $i - 1$, i, and $i + 1$. Each strip is a region of a spectrum corresponding to the amide nitrogen plane and proton resonance for the indicated residue. As seen in Figure 28.1, HNCACB spectra correlate the amide of each residue with the α- and β-carbons from the same and previous residues, while CBCA(CO)NH spectra correlate the amide of each residue with the α- and β-carbons from the previous residue. Data was kindly provided by Prof. Brian Sykes, University of Alberta, Canada.

have been developed. Semiautomated assignment programs, such as ANSIG (Helgstrand *et al.*, 2000) and Smartnotebook (Slupsky *et al.*, 2003), suggest possible sequential assignments to be visually verified and confirmed by the user. Automated assignment programs produce the assignment for spin systems in the protein from its amino acid sequence and a peak list. Examples are PASTA (Leutner *et al.*, 1998), TATAPRO (Atreya, Chary and Govil, 2002), MARS (Jung and Zweckstetter, 2004), and MATCH (Volk, Hermann and Wüthrich, 2008).

Such methods still require some level of user input, and in most cases not all amino acid residues in a protein can be assigned automatically.

Once the backbone has been assigned, the side chains in the protein need to be assigned for structural determination. This is achieved through total correlation spectroscopy TOCSY-based experiments that correlate, through bonds, the nuclei already assigned to the rest of the side chain.

28.3.2
Chemical Shift Assignment in Nucleic Acids

Methods for chemical shift assignment of nucleic acids have been reviewed by Flinders and Dieckmann (2006), Tzakos *et al.* (2006), Fürtig *et al.* (2003), Cromsigt *et al.* (2001), Wijmenga and Van Buuren (1998), and Varani, Aboul-Ela and Allain (1996). These reviews also cover structural determination methods for nucleic acids.

Assignment of nucleic acids starts with the nucleobase spin systems, followed by correlation of each nucleobase to the corresponding sugar spin system, using HCN triple-resonance experiments in ^{13}C, ^{15}N-labeled nucleic acids. Assignment of the sugar spin system is then completed using a combination of HCCH-TOCSY and HCCH-COSY-based experiments (Flinders and Dieckmann, 2006). Sequential connections between nucleotides are made using nuclear overhauser effect spectroscopy (NOESY) experiments, or HCP and HCP-TOCSY experiments, which correlate the backbone ^{31}P nuclei to hydrogen and carbon atoms.

Base pairings can be assigned from the imino proton of guanines and uracyls, which have characteristic chemical shifts between 10 and 15 ppm. These protons exchange with water, and therefore can only be observed when involved in hydrogen bonding. A homonuclear 2D NOESY experiment correlates those resonances with neighboring protons, both from the nucleotide involved in the base pairing and from sequential nucleotides in the same strand (Tzakos *et al.*, 2006). HNN-COSY experiments correlate the nucleotides in a base pair using scalar couplings between the nitrogen atom of the hydrogen bond acceptor and the nitrogen and hydrogen of the hydrogen bond donor (Dingley and Grzesiek, 1998; Pervushin *et al.*, 1998). Both methods are illustrated in Figure 28.3. ^{13}C, ^{15}N edited or filtered 2D and 3D NOESY experiments are used to decrease overlap in NOESY spectra, and identify NOEs for assignment and structure determination (Fürtig *et al.*, 2003; Flinders and Dieckmann, 2006).

In single-stranded RNA, the experiments based on base pairing are not possible, and assignment is much more difficult. The lack of base stacking also leads to decreased spectral dispersion. Isotopic labeling of RNA is essential for sequential assignment of single-stranded regions, such as bulges in the RNA structure.

28.3.3
Chemical Shift Assignment in Carbohydrates

Carbohydrates are more diverse than either proteins or nucleic acids in their basic components and connections. A large number of sugars form the possible basic units of carbohydrates and the potential for branched carbohydrate chains indicate that there is not always a primary sequence in the way that polypeptides

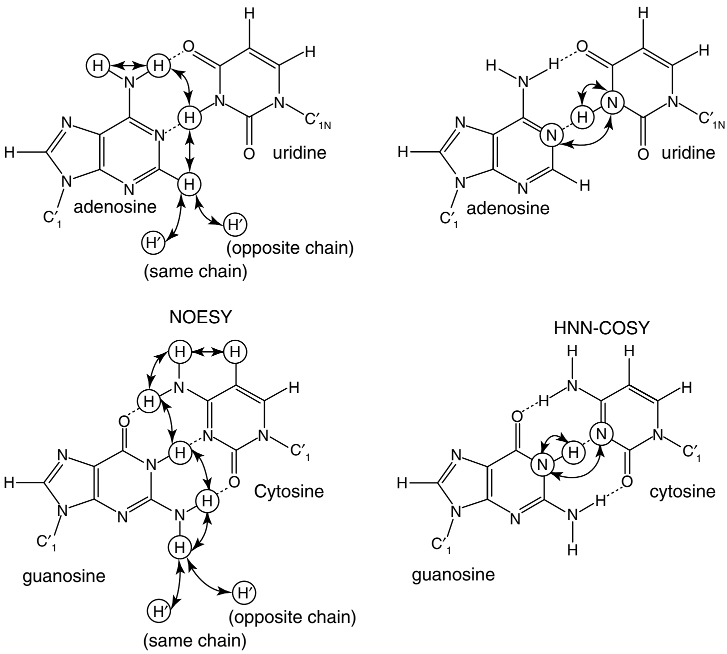

Fig. 28.3 Determination of base pairing in nucleic acids using NOESY or HNN-COSY spectra. Magnetization transfer steps are represented by arrows. In the NOESY experiment, magnetization transfer between protons occurs simultaneously in both directions of each arrow. During the HNN-COSY experiment, magnetization is transferred from the imino proton to the covalently bonded nitrogen, from there to the hydrogen-bonding nitrogen, and back to the imino proton for data acquisition.

and polynucleotides possess. This has led to different approaches to assignment being developed by different groups (Duus, Gotfredsen and Bock, 2000).

Some of the issues in chemical shift assignment of carbohydrates are related to the difficulty in obtaining labeled samples of carbohydrates. A number of experiments can be done using the natural abundance of ^{13}C, but this limitation greatly restricts the size of the molecules that can be studied. The labeling schemes described for carbohydrates in Section 28.2.1 can help to overcome this obstacle.

Unlike proteins and nucleic acids, the sequence of monomers in a carbohydrate is not clearly coded in the organism's genome. This means that the process of assignment often starts with the use of multiple techniques in addition to NMR, such as mass spectroscopy, to determine the sequence of sugar monomers in a carbohydrate.

A summary of the steps used for chemical shift assignment in carbohydrates was reviewed by Duus, Gotfredsen and Bock (2000). In short, the process for oligosaccharides starts by finding a characteristic chemical shift for each sugar monomer in the ^{1}H, and using experiments that correlate nuclei through bonds to assign the other atoms in each monomeric unit. Such experiments can include HSQC/HMQC/HMBC to correlate carbon and protons, TOCSY, DQF-COSY, and ^{13}C-edited HSQC-TOCSY. Intraresidue NOEs or ROEs (rotating-frame NOEs) can also be useful to assign individual resonances inside a monomer, and the anomeric conformation of a sugar can be determined from ^{13}C chemical shifts, and from a number of scalar coupling constants.

More recently, the H2BC (heteronuclear 2-bond correlation) experiment has been shown to provide unambiguous assignments and simplify carbohydrate spectra by correlating protons and carbons over two bonds (Petersen *et al.*, 2006).

A strategy that can be used for carbohydrate assignment is to decrease the dimensionality of the experiment, decreasing acquisition time and focusing on a desired region. With the use of selective pulses, a 1D spectrum can be acquired corresponding to the trace of the 2D spectrum in a specific frequency, reflecting the same connectivities. Similarly, a 2D plane of a 3D spectrum can be acquired, focusing in a specific region of the spectrum (Uhrin and Barlow, 1997; Roumestand *et al.*, 1999).

28.4
Structural Restraints

28.4.1
Nuclear Overhauser Effect

The nuclear overhauser effect (NOE) (Overhauser, 1953) arises from cross-relaxation processes that allow the transfer of magnetization from a nucleus to other nearby nuclei, through dipolar relaxation mechanisms. The build-up of an NOE between two spins i and j is given by the cross-relaxation rate, σ_{ij}, which is the difference between the rate for the flip-flip transition, W_2 (in which both spins are flipped in the same sense), and the rate for the flip-flop transition, W_0 (in which the spins are flipped in opposite senses):

$$\sigma_{ij} = (W_2 - W_0) \qquad (28.1)$$

In the homonuclear case, the resonance frequency of the two spins can be considered to be the same, ω_0, and the cross-relaxation rate will be

$$\sigma_{ij} \propto \frac{1}{r_{ij}^6}\left\{6J(2\omega_0) - J(0)\right\} \qquad (28.2)$$

where r_{ij} is the internuclear distance, $J(2\omega_0)$ is the spectral density function at twice the resonance frequency of the spins (for W_2), and $J(0)$ is the spectral density function at frequency zero (for W_0).

As it can be seen above, NOE build-up rates are proportional to the inverse of the sixth power of the distance, and therefore can be used to calculate distance restraints for structural calculations. NOESY experiments are used to measure the NOE build-up rates, and have a mixing time during which the magnetization evolves according to the NOE. However, the linearity between NOE build-up rates and distance is only complete when the mixing time is zero. In reality, the mixing time is kept small enough to allow this linearity approximation to be used. As the size of the molecule increases, and with it the rotational correlation time, dipolar relaxation mechanisms become more efficient, and the linear approximation is valid for shorter times. Spin diffusion (in which a peak in the NOESY spectrum is created via an indirect relaxation path) also increases with mixing time, as does intensity of the NOE signal before other relaxation processes cause it to diminish. Therefore, mixing times need to be optimized according to the characteristics of the molecule.

Multidimensional NOESY spectra correlate nuclei that are close in space, independently of being connected by bonds. Two-dimensional NOESY spectra correlate protons through space, and are useful for the structural determination of relatively small molecules, including small proteins. As the number of hydrogens in a molecule grows, so does the number of peaks, which start to overlap in a two-dimensional spectrum, and three-dimensional ^{15}N- or ^{13}C-edited NOESY spectra become necessary for resolving the signals. In the three-dimensional spectrum, the peaks from a two-dimensional NOESY spectrum are spread into planes according to the chemical shift of the nitrogen or carbon to which one of the protons is attached (Marion *et al.*, 1989a; Marion *et al.*, 1989b; Zuiderweg and Fesik, 1989).

Each peak in a NOESY spectrum represents a correlation through space between two nuclei, independently of a connection through bonds, and can be used to determine distance restraints for structure calculation. After the peaks in a NOESY spectrum are assigned to the corresponding atoms in the molecule, distance restraints are created for the nuclei correlated by each peak. This step can be time consuming, and often requires multiple rounds of interaction, because commonly many NOEs cannot be unambiguously assigned with chemical shift information only. This problem worsens with increasing protein size, or chemical shift imprecision (Mumenthaler *et al.*, 1997). To circumvent this problem, a preliminary structure is often calculated based on the unambiguously assigned residues, and this structure is then used as additional information to resolve NOE assignment ambiguities, based on atom proximity in the preliminary structure. Alternatively, ambiguous assignments can be used if the different assignment possibilities are taken into account (Nilges, 1995).

This process can be automated in available software for the structural determination of proteins using iterative rounds of automated NOESY assignment, distance restraint determination, and structure calculation. Two examples of this type of software are CANDID (Herrmann, Güntert and Wüthrich, 2002) and ARIA (Linge *et al.*, 2003), which differ amongst other things in their strategies for dealing with multiple assignment possibilities in the calculation process.

Owing to the relationship between distance and build-up rates, the strength of the NOE peaks decreases rapidly as the distance between nuclei increases (Wüthrich, 1986). In practice, that means that peaks in a NOESY spectrum of a biological macromolecule represent a correlation between two nuclei that are no more than 6 Å apart, and that peaks in the same spectrum can be calibrated according to their intensity to reflect the distance between the two nuclei being correlated. A common method for calibrating the distance according to the peak volume involves dividing the peaks into three classes (weak, medium, strong), each corresponding to a range of distances (Clore *et al.*, 1985; Williamson *et al.*, 1985). A different method involves assigning peaks corresponding to nuclei with known distances (such as between the amide proton of one residue, and the α-proton of the previous residue), and use that as a reference to calibrate the remaining distances (Gagné *et al.*, 1997). In either method, it is better to set the upper limit of each distance too large than too small. Distance restraints that are too tight result in distorted molecular structures, while the presence of enough restraints will lead to the correct structure, even if they are too loose compared to the actual distances (Wijmenga and Van Buuren, 1998; Clore and Gronenborn, 1991).

Distance restraints based on NOE correlations are the staple of protein structure determination by solution NMR, and many proteins structures have been determined relying exclusively on them. For nonglobular macromolecules, however, they often do not offer enough information for a well-defined structure. NOE distance restraints do not extend beyond 6 Å and a good structure requires a large number of distance restraints between atoms that are distant from each other in the original residue sequence, but close in space. For elongated structures, cumulative uncertainties in the short-distance NOE restraints can lead to large uncertainties in the structure as a whole, requiring the use of other structural restraints. Examples of this situation are nucleic acids, in which pairwise interactions do not provide the same "long-range" restraints, carbohydrates, and some elongated helical proteins. In those cases, the use of other structural restraints discussed below becomes essential.

When the molecule needs to be deuterated to increase the transverse relaxation time, ^{1}H nuclei will only be available at positions that exchange with water. In this case, the low number of hydrogen nuclei limits the number of NOE restraints. To increase the number of protons available for distance restraints in proteins, while retaining the relaxation advantages of a mostly deuterated protein, different labeling schemes have been developed, that lead to deuteration of most of the protein, with hydrogens present in methyl groups on side chains (Tugarinov, Hwang and Kay, 2004; Tugarinov and Kay, 2004).

28.4.2
Torsion Angles

Using the Karplus relationship (Karplus, 1959), torsion angles can be calculated from three-bond scalar coupling between the nuclei involved. A number of pulse sequences have been developed to measure scalar couplings between relevant nuclei, and the corresponding Karplus relationships have been calibrated.

The scalar couplings $^3J_{\mathrm{HN}\alpha}$, $^3J_{\mathrm{HNCO}}$, $^3J_{\mathrm{HNC}\beta}$, and $^3J_{\mathrm{C}i-1\mathrm{H}\alpha i}$ correlate to backbone ϕ angles, and $^3J_{\mathrm{N}i\mathrm{H}\alpha i-1}$ correlates to ψ angles in proteins (discussed in Smith *et al.*, 1996). $^3J_{\mathrm{HN}\alpha}$ can be measured from the HNHA experiment to generate ϕ structural restraints (Barnwal *et al.*, 2007; Kuboniwa *et al.*, 1994; Pardi *et al.*, 1984). Restraints for side chain χ_1 angles can be derived from $^3J_{\mathrm{NH}\beta}$, measured from the HNHB experiment (Archer *et al.*, 1991). Restraints for ψ angles can be derived from the intensity ratio $d_{\mathrm{N}\alpha}/d_{\alpha\mathrm{N}}$ in a ^{15}N NOESY-HSQC experiment (Gagné *et al.*, 1994).

Alternatively, main-chain torsion angles can be calculated from chemical shift values by computer programs that use a database of protein structures and chemical shift values, such as TALOS (Cornilescu *et al.*, 1999), SHIFTOR (Neal *et al.*, 2006), and the more recent DANGLE (http://dangle.sourceforge.net/).

Numerous experiments can be used to measure scalar coupling constants in carbohydrates, as reviewed by Bush *et al.* (1999) and Duus, Gotfredsen and Bock (2000), and new experiments and Karplus correlations are still being determined (see Coxon, 2007; Mobli and Almond, 2007, for recent examples). Three-bond and one-bond coupling constants can be used to determine the anomeric configuration of the sugar (Duus, Gotfredsen and Bock, 2000).

In nucleic acids, the sugar pucker mode and a number of torsion angles can be determined from scalar couplings. The correlations between a large number of angles and the relevant coupling constants, and the experiments needed to determine such coupling constants, have been reviewed by Wijmenga and Van Buuren (1998). Phosphodiester backbone angles α and ζ in oligonucleotides can be calculated from cross-correlated relaxation rates of ^{1}H, ^{13}C-dipole, dipole and ^{31}P-chemical shift anisotropy (Richter *et al.*, 2000).

28.4.3
Residual Dipolar Couplings (RDCs)

While interaction between two nuclei connected through bonds leads to line splitting because of scalar coupling, the interaction of nuclei through space leads to dipolar coupling, which arises from the interaction between the two magnetic dipoles of the nuclei. The magnitude of an observed dipolar coupling is given by the following equation:

$$D_{ij} = \frac{-\mu_0 \gamma_i \gamma_j \hbar}{4\pi^2 r^3} \left\langle \frac{3\cos^2\theta - 1}{2} \right\rangle \tag{28.3}$$

where γ is the gyromagnetic ratio of the interacting spins i and j, r is the distance between the nuclei, and θ is the angle between the applied magnetic field and the internuclear vector.

In solution NMR, the splitting due to dipolar coupling is not seen, being averaged to zero by rotational diffusion, unlike scalar coupling. (The splitting caused by scalar coupling is normally eliminated by decoupling techniques, but can be seen in undecoupled spectra.) When the molecules in the sample are partially aligned, some splitting due to dipolar coupling can be observed, named as residual dipolar coupling (RDC). By keeping the degree of alignment small, but nonzero, it is possible to have measurable effects from RDCs, and still keep the simplified spectrum obtained from motionally averaged molecules. From RDCs, orientational restraints can be derived, and are widely used in structural determination of proteins, carbohydrates, and nucleic acids. Different aspects of the use of RDCs in structural determination of biological macromolecules have been reviewed by Bax and Grishaev (2005), Blackledge (2005), Lipsitz and Tjandra (2004), and Prestegard *et al.* (2005). The influence of dipolar coupling on peak splitting in biological macromolecules was first shown for the main-chain amides of cyanometmyoglobin, a protein that spontaneously shows detectable partial alignment within the magnetic field from an NMR spectrometer (Tolman *et al.*, 1995).

The effect of alignment on main-chain amide ^{15}N splitting in proteins provides a good example of RDC measurements. In a splitting-enhanced {^{1}H, ^{15}N}-HSQC spectrum (undecoupled in the ^{15}N dimension) (Tolman and Prestegard, 1996), splitting of the ^{15}N resonance in protein main-chain amides can be observed, and the coupling constant can be measured from the distance between the peaks. In solution NMR, when the molecules are tumbling isotropically, this splitting will reflect only the scalar coupling constant $^{1}J_{\mathrm{HN}}$ between the proton and nitrogen. When the molecules are partially aligned by any method, the splitting will reflect the sum of the scalar coupling, $^{1}J_{\mathrm{HN}}$, and the residual dipolar coupling, D_{HN}. Another method to measure the splitting involves the use of in-phase/antiphase (IPAP) spectra, in which the two components of the doublet are seen in separate spectra, therefore not increasing spectral complexity compared to the decoupled spectrum (Ottiger *et al.*, 1998). In *J*-resolved spectroscopy (Aue *et al.*, 1976), the proton resonances evolve with the chemical shift in t_2, and with *J*-coupling in t_1. Unlike the HSQC experiments, that take advantage of heteronuclear signal dispersion in the indirectly detected dimension, *J*-resolved spectroscopy requires good dispersion in the proton spectrum.

From Eq. (28.3) above, the angle between the bond vector and the magnetic field can be determined. It is important to notice that there are always two opposite orientations of the bond vector that satisfy the equation for any RDC value, and therefore RDC information should be obtained from multiple alignment media for structural calculations, or supplemented with other experimental distance information (Blackledge, 2005). RDC information can be used for structural calculation using simulated annealing programs (Tjandra and Bax, 1997). Orientational restraints are very important for the structural determination of carbohydrates, nucleic acids, and large deuterated proteins, for which it is usually not possible to acquire enough NOE distance restraints to resolve the structure. Numerous pulse sequences are available for the determination of RDCs between different nuclei in nucleic acids (reviewed by Latham *et al.*, 2005).

Alignment of molecules with the magnetic field can be generated with the use of paramagnetic metals (Tolman *et al.*, 1995), or by restricting the movement of the molecule with alignment media, which will result in alignment according to the shape of the molecule. Different alignment media that can be used in biological samples include liquid crystal media (Tjandra and Bax, 1997), a suspension of filamentous bacteriophage (Hansen *et al.*, 1998), lipid bicelles (Sanders *et al.*, 1994; Bax and Tjandra, 1997), or stretched polyacrylamide gels (Sass *et al.*, 2000; Tycko *et al.*, 2000).

28.4.4
Hydrogen Bonds

Experimentally detected hydrogen bonds can provide useful structural restraints. In proteins, hydrogen bonds patterns can reveal secondary structure, while in nucleic acids, hydrogen bonds are present in every base pairing. They can be measured either indirectly, from the exchange with the solvent (for example, in Krishna *et al.*, 2004), or directly, via experiments that transfer magnetization across the hydrogen bond through the two-bond scalar couplings (Grzesiek *et al.*, 2004). For structural determination of nucleic acids, the use of NMR experiments that transfer magnetization through H-bond scalar couplings has become widespread.

28.4.5
Paramagnetic Centers

Paramagnetic centers in biological macromolecules can occur naturally, as in metalloproteins, or be added by different methods, such as by replacing a naturally-occurring diamagnetic ion with a paramagnetic ion (Lee and Sykes, 1983), adding a nitroxide spin label (Battiste and Wagner, 2000; Gaponenko *et al.*, 2000), or by engineering a binding site for a paramagnetic ion (for examples, see Ma and Opella, 2000; Donaldson *et al.*, 2001; Wöhnert *et al.*, 2003; Su *et al.*, 2008). Different techniques have been developed to incorporate paramagnetic centers in nucleic acids, for instance using 4-thiouracil or 4-thiothymidine, which is then coupled to a spin label via the sulfur group (Ramos and Varani, 1998), or using site-specifically 2′-amino-modified nucleic acids (Edwards and Sigurdsson, 2007). The use of chemical modifications to create lanthanide-binding sites for paramagnetic structural restraints is becoming increasingly popular (Otting, 2008).

Contact shifts caused by through-bond interaction between the nucleus and the paramagnetic center can be a powerful source of structural information. The presence of an unpaired electron in an NMR sample will also affect the chemical shifts and relaxation of other nuclei close enough to the unpaired electron to present dipolar interactions with it. In practice, this can be as much as 20 Å, which is a longer distance than can be observed by NOE interactions. Having a paramagnetic center in a known position of the molecule, then, can be an effective way to determine structural constraints for nuclei located at close or medium distance from that position. The effect of a paramagnetic center on nearby nuclei can be used to calculate a number of constraints for structural determination, based on pseudocontact shifts, relaxation enhancement, contact shifts, and cross-relaxation (Bertini *et al.*, 2002; Bertini *et al.*, 2005). Pulse sequences may have to be modified when characterizing biomolecules containing paramagnetic centers.

Paramagnetic centers also cause the molecules to align along the external magnetic field, and this alignment can used to extract residual dipolar couplings (Tolman *et al.*, 1995). The combination of RDC and paramagnetic restraints has been used to determine a protein structure without NOE restraints (Hus *et al.*, 2000). As with RDC, the use of paramagnetic restraints can be very beneficial to molecules for which it is not possible to obtain sufficient NOE restraints for accurate structural determination, such as nucleic acids.

28.4.6
Structural Information from Chemical Shifts

Different conformations in biomolecules can have strong effects on the chemical shift values of nuclei in specific positions, and this information can be used to help structural determination. In proteins, regions of secondary structure can be predicted from the chemical shift index (Wishart and Nip, 1998; Wishart and Case, 2001). In brief, chemical shift values of $^{1}H_{\alpha}$, $^{1}H_{\beta}$, $^{1}H_{N}$, $^{13}C_{\alpha}$, $^{13}C_{\beta}$, ^{13}CO, and ^{15}N for each residue can be compared to typical random coil values, and the difference is usually indicative of the presence or absence of helical or sheet secondary structure. For an element of secondary structure to be predicted reliably, it should be predicted by at least three amino acid residues in a row. The use of multiple nuclei also increases the reliability of the method. Methods to extract information from chemical shift values for proteins have been reviewed by Szilágyi (1995) and Case (2000). A number of uses of chemical shift values to aid in assignment and structural determination of nucleic acids have been described by Wijmenga *et al.* (1997), Altona *et al.* (2000), Cromsigt *et al.* (2001) and Fürtig *et al.* (2003).

In partially oriented samples, chemical shift anisotropy (CSA) can also yield structural information (Lipsitz and Tjandra, 2001; Lipsitz and Tjandra, 2003; Ying *et al.*, 2006; Choy *et al.*, 2001; Cornilescu and Bax, 2000; Wu *et al.*, 2001; Yu and Prestegard, 2006). Chemical shifts in a molecule are usually anisotropic by nature, depending on the orientation in the magnetic field. When a molecule tumbles isotropically in solution NMR, the averaging of chemical shift values gives rise to the sharp lines seen in solution NMR. In solid state NMR, the anisotropy can be seen in the "powder pattern" if the molecules are not oriented. In partially aligned samples, the effect of CSA can be seen as an offset of the chemical shift in relation to its value in an isotropic sample.

Recently, methods for determining protein structures based on chemical shift values alone have been developed, CHESHIRE (Cavalli *et al.*, 2007), and CS-ROSETTA (Shen *et al.*, 2008). Both methods use molecular fragment replacement approaches, used previously on the ROSETTA *ab initio* structure prediction method (Bradley *et al.*, 2005) and to analyze RDCs (Rohl and Baker, 2002; Delaglio *et al.*, 2000), amongst other applications. By eliminating the need to acquire separate spectra for structural restraints, the experimental time needed to determine protein structures can be greatly reduced, and structural determination by NMR can be extended to less stable proteins. A current limitation of this approach is protein size; both methods are effective only for proteins up to 15 kDa. The newly developed CamDock procedure extends this approach to protein-protein complexes (Montalvão *et al.*, 2008).

28.5
Molecular Modeling and Structure Calculation

Structural restraints determined as described above are used to calculate the structure by molecular modeling. Simulated annealing and molecular dynamics, either in the Cartesian space of atomic positions or in the torsion angle space, are the most common methods for structure calculation from restraints derived from NMR experimental data, starting from an extended structure or from a preliminary model (Clore and Gronenborn, 1998). The different experimental restraints are incorporated into the calculations as pseudo-energy functions added to the molecular energy representations, forming a hybrid energy term $E_{\text{hybrid}} = E_{\text{phys}} + w_{\text{data}} E_{\text{data}}$, where E_{phys} is the sum of physical energy terms such as bond length and nonbonded interactions, and E_{data} assesses the consistency between the model structure and the different types of experimentally measured restraints (Brünger and Nilges, 1993).

The initial high-temperature stage of the simulated annealing calculations allows for wider exploration of the conformational space by overcoming energy barriers, followed by slow cooling while sampling the conformational space by molecular dynamics. Molecular modeling in Cartesian coordinates is based on the numerical solution of Newton's equations of motion, and the position of each atom is modeled with energy representations for bond angles and lengths (Nilges *et al.*, 1988). Molecular dynamics in the torsion angle space assumes the distance and bond angle between the pair of atoms connected by a bond to be fixed, and allows them to rotate around the bond. The reduced number of degrees of freedom and larger time steps in the simulated annealing lead to faster calculations and convergence (Stein *et al.*, 1997). Common programs that use molecular dynamics for structural calculations from NMR data include Xplor-NIH (Schwieters *et al.*, 2003), CNS (Brünger, 1998; Brunger, 2007) and CYANA (Güntert, 2004), or its predecessor DYANA (Güntert *et al.*, 1997). While computational power was a limiting factor when these methods were first developed, now these calculations are trivial and can be performed in most PCs with the appropriate software.

The iterative steps of NOESY peaks assignment and structural calculation have been automated together in a number of programs, such as ARIA (Nilges *et al.*, 1997; Linge *et al.*, 2003), CANDID (Herrmann *et al.*, 2002), CYANA (Güntert, 2004), and others (Güntert, 2003). These programs require a chemical shift list as input, with the resonance values for the atoms that will be involved in NOE contacts.

More recently, methods based on molecular fragment replacement have been developed for proteins, in which model structures for each fragment are retrieved from a database according to the fragment sequence and experimental data (Bowers, Strauss and Baker, 2000). This is the same approach used for *ab initio* protein structure calculation by the program ROSETTA (Simons *et al.*, 1997; Simons *et al.*, 1999) and has been applied to structure calculation based on chemical shifts only (Cavalli *et al.*, 2007; Shen *et al.*, 2008; Montalvão *et al.*, 2008) and to the analysis of RDC data (Rohl and Baker, 2002). These calculations are more computationally demanding than molecular dynamics-based methods.

Biomolecular structures calculated using any of the methods above need to be validated, and there are a number of programs for structural validation such as VADAR (Willard *et al.*, 2003), PROCHECK-NMR and AQUA (Laskowski *et al.*, 1996), and WHAT IF (Doreleijers *et al.*, 1999; Vriend, 1990).

29.1
Introduction

29.1.1
Concept of Mass Spectrometry

Mass spectrometry (MS) includes all techniques for the determination of the masses of single atoms, molecules and their fragments or their associates. The mass spectrometric experiment comprises the sequence of (i) generation of gas phase ions from either inorganic or organic compounds by any suitable method, (ii) separation of these ions by their *mass-to-charge ratio* (m/z), and (iii) detection of the ions qualitatively and quantitatively by their respective m/z and abundance. Each of these steps can be performed in various ways. The first step, *ionization*, can be achieved thermally, by electric fields or by impact of energetic particles such as electrons, small ions or heavy cluster ions, neutral atoms, or photons. The second step, *ion separation by m/z*, is effected by static or dynamic electric or magnetic fields and combinations thereof, forcing the ions to follow a trajectory characteristic of their respective m/z value. Finally, the detection of the ions is accomplished by transforming their impact onto a detector or the image current of their motion into an electric current that is then translated into a signal, a so-called peak, in the output of the *mass spectrometer*, the *mass spectrum* (Figure 29.1). Commonly, the signals are normalized to *relative intensity* by setting the most intensive peak, the *base peak*, to 100 %. A mass spectrum can be represented as bar graph, profile data, or m/z versus intensity listing.

According to these functional requirements, a mass spectrometer can be seen as composed of three basic moieties: (i) the *ion source*, (ii) the *mass analyzer*, and (iii) the *detector*. In contemporary mass spectrometers, these moieties are operated under the common control of a computer system. The principles, types, and operational modes of mass spectrometers are outlined in Chapter 23.

29.1.2
Goal of Mass Spectrometry

The ultimate goal of MS is to identify an analyte from the molecular or atomic mass(es) of its constituents. Knowing just the mass can be sufficient for the identification of elements and for the determination of the molecular formula

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

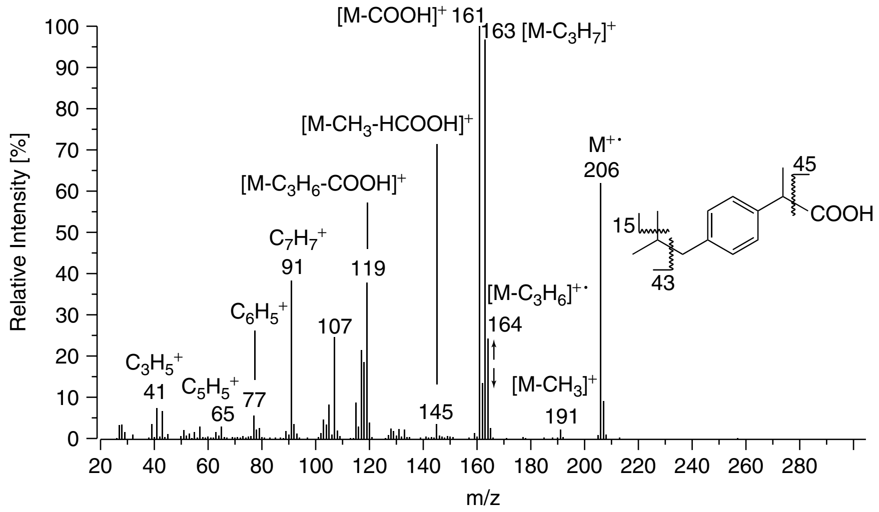

Fig. 29.1 The 70-eV electron ionization mass spectrum of the over-the-counter drug ibuprofen illustrates the principle of MS. The ionized molecule, that is, the molecular ion, fragments along several competing pathways to yield fragment ions that may themselves undergo further decomposition. The *m/z* values observed can – with more or less ease – be correlated to ionic compositions and eventually structures. Putting the puzzle together may reveal the structure of the analyte.

of an analyte. The relative abundance of isotopomers delivers strong supportive information to include or to rule out certain elements in such a formula and to estimate the number of atoms of a contributing element. Fragmentation of molecular species under the conditions of certain mass spectrometric experiments can deliver information on structure such as the connectivity of atoms within smaller molecules, the identification of functional groups, the (average) number and eventually the sequence of constituents of macromolecules, and in some cases even on their three-dimensional structure.

29.1.3
Mass Spectrometry at a Glance

MS has undergone tremendous transformations since J. J. Thomson's work marked its beginning in the early twentieth century (Grayson, 2002). MS developed from a mere mass measurement technique of physicists to one of the major analytical methods in chemistry and life sciences, while still preserving its importance in its fields of origin. Obviously, the fact that MS can be adapted in a very flexible manner to answer analytical questions of vast diversity allows it to become a whole branch of spectroscopy.

- MS serves for elemental identification and isotopic abundance measurement of both short-lived and stable species, thereby gaining relevance not only in physics and radiochemistry but also in geochemistry and more recently in life sciences.
- MS allows for the identification and structural characterization of small

molecules or for very large molecules as provided by either physiological processes or polymer chemistry.
- Mass spectrometric experiments can be stacked. Thus, a mass-selected ion can be studied by *tandem MS* and any product ion of this MS/MS (or MS^2) experiment may eventually be subjected to a third level (MS^3) and so forth (MS^n).
- MS, and especially tandem MS, also provides an elegant means for the study of unimolecular as well as bimolecular reactions of gas phase ions and for the determination of ion energetics.
- MS can be directly coupled to separation methods such as gas chromatography (GC) and all types of liquid chromatography (LC). *Coupling* or *hyphenation* to yield GC-MS or LC-MS instrumentation delivers high selectivity and low detection limits for the analysis of trace compounds in complicated matrices or the deconvolution of complex mixtures, making the hyphenated methods to become a major analytical tool.
- Mass spectra can be obtained from micrometer-sized areas on surfaces. This way, the lateral distribution of compounds on surfaces ranging from microelectronics to slices of tissue can be translated into images that in turn can be correlated to optical images of those samples. This is known as *mass spectral imaging*.
- Mass spectrometers can be very small. Miniaturization has led to portable instruments for environmental on-site analysis, detection systems for explosives and warfare chemicals, and last but not the least for many space missions.

In particular, the life sciences had and still have great impetus on the development of the manifold approaches to expand the mass range to higher molecular weights and increasingly fragile molecules. Environmental and pharmaceutical research present the driving force for the ever-improving limits of detection. There is ongoing research on methods of ion sampling, ion generation, and subsequent ion transfer into mass analyzers with better performance. Every application has unique requirements for the exact way in which the mass spectrometric experiment is performed, that is, on how to acquire a mass spectrum of a given analyte. MS has many facets and does not reveal itself from a single perspective. Like a view onto a globe does not reveal the complete surface of our planet, but roughly just one continent at a time, MS needs to be explored from various vantage points.

29.1.4
Aims and Scope

This chapter is intended to complement the seemingly abstract description of mass spectrometers by putting them into a real-world context of analytical applications. Nonetheless, the vast number of methods in MS and the plethora of applications of MS cannot be comprehensively covered within a single chapter. However, this chapter is intended to provide a convenient entry into the realm of MS by highlighting basics, relevant techniques, and applications. Therefore, the chapter deals with

- isotopes, isotopic abundance, and isotopic mass;
- ionization processes;

- ionization methods and the corresponding ion sources;
- the behavior of the ions formed by these ionization processes; and
- applications of tandem MS.

29.2
The Role of Isotopes in Mass Spectrometry

29.2.1
Isotopes

Elements are classified by (i) their *atomic number* Z (subscripted prefix at the element symbol, e.g., $_6C$), which is equal to the number of protons in the nucleus and also is equal to the number of electrons of a neutral atom and (ii) their *mass number* A (superscripted prefix at the element symbol, e.g., ^{12}C). The mass number is given by the sum

$$A = Z + N \tag{29.1}$$

where N is the number of neutrons in the nucleus.

An element is termed *monoisotopic* if there exists only one nuclide of this element, that is, all of its atoms have equal A. This is the case for 20 of 83 naturally occurring stable elements, for example, F, Na, P, I, or Cs. If radioactive isotopes are also taken into account, there is no element left as monoisotopic. Elements with two naturally occurring stable nuclides are termed *di-isotopic,* for example, Li, B, Cl, Cu, Br, Ag, or Ir, and the others are termed *polyisotopic,* for example, Ru, Sn, or Xe. However, isotopes are distinguished by their mass number, the difference in mass being due to the varying number of neutrons in the nuclei of an element.

Isotopes of different elements sharing the same mass number are termed *isobars,* for example, ^{40}Ar, ^{40}K, and ^{40}Ca. The term also applies to molecules having different compositions yielding equal (nominal) mass, for example, CO, N_2, and C_2H_4.

29.2.2
Atomic Mass Scale

MS has been the key in establishing the atomic mass scale from the beginning (de Laeter, De Bièvre and Peiser, 1992). The atomic mass scale has been fixed relative to carbon. According to the Union of Pure and Applied Chemistry (IUPAC), the *unified atomic mass* [u] is defined as 1/12 of the mass of one atom of the nuclide ^{12}C in its electronic ground state. By defining the molar mass of carbon-12 exactly as 0.012 kg mol^{-1}, the mass of one atom is obtained by dividing this by the Avogadro constant. Therefore, 1 u equaling 1/12 of the atom's mass is obtained as $1\ u = 1/12 \times 0.012\ kg\ mol^{-1}/6.022136 \times 10^{23} = 1.660540 \times 10^{-27}$ kg. Instead of "u" the unit *dalton* (Da) (to honor J. Dalton) is also in use.

29.2.3
Isotopic Patterns

MS separates isotopes by mass, and thus, the isotopic composition of an element is directly reflected by its mass spectrum. In molecules, the isotopes of all atoms are contributing to the isotopic pattern, some more like chlorine and some less like carbon or hydrogen. Consequently, the detection of a molecular ion or fragment translates into a spectrum representing the contribution of all isotopes (Figure 29.2). It is possible

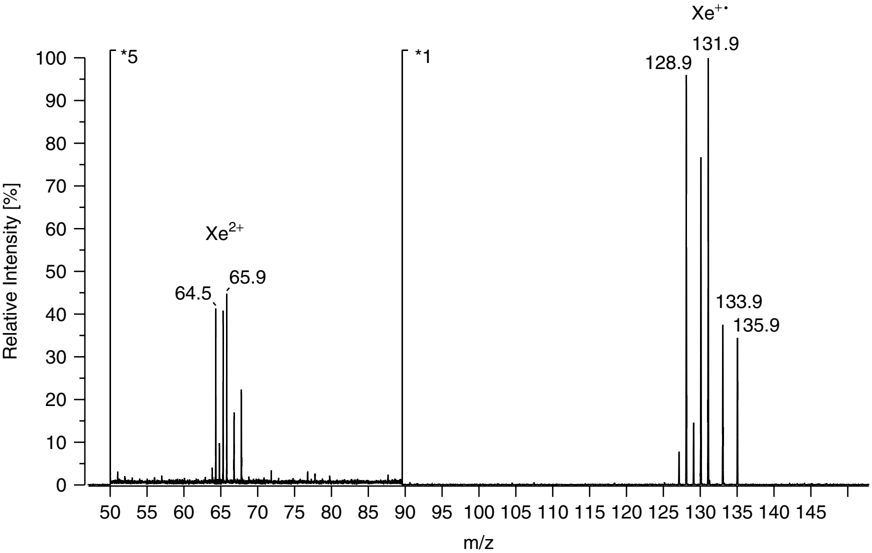

Fig. 29.2 Seventy electronvolts electron ionization mass spectrum of xenon gas. The singly as well as the doubly charged atomic ions reflect the isotopic composition of Xe from their isotopic patterns. The position of Xe^{2+} is at half m/z of $Xe^{+\bullet}$ and the distance between adjacent peaks of Xe^{2+} ion is half that of $Xe^{+\bullet}$ because $z = 2$ in m/z. Note that the intensity scale is increased by a factor of 5 for the doubly charged ion.

to calculate the isotopic pattern of a molecule based on statistical methods, because the isotopic composition of the elements is accurately known in most cases. Vice versa the experimental isotopic patterns can be fitted to theoretical distributions. In fortunate cases, in some cases, the molecular formulas of small molecules, say up to 200–300 u, can be assigned from their isotopic pattern alone.

29.2.4
Accurate Mass

Mass numbers are integers. The *accurate mass* of an isotope, however, slightly deviates from the nominal value of *A* due to the conversion of mass into energy during nucleation. The binding energy per nucleon steeply increases along the mass numbers from ^{2}H to its maximum around ^{56}Fe and then decreases again slightly up to ^{238}U (Figure 29.3).

Translation into isotopic mass reveals that for light elements mass is by some 10^{-3} u above the nominal value (^{1}H or ^{14}N), whereas it is by some 10^{-3} u (^{19}F) to 10^{-1} u (^{127}I) below for heavier elements. This *mass defect* was unveiled by Aston who had already discovered 212 of all 287 stable isotopes (Table 29.1).

To calculate the accurate mass of an ion, the electron mass ($m_e = 9.10939 \times 10^{-31}$ kg or 0.0005486 u) needs to be subtracted from the accurate mass of the corresponding neutral in the case of positive ions or added in the case of negative ions (cf. Figure 29.27).

Measuring the mass of ions with sufficient accuracy (often 0.5–10 ppm) allows to identify isotopes and molecules by

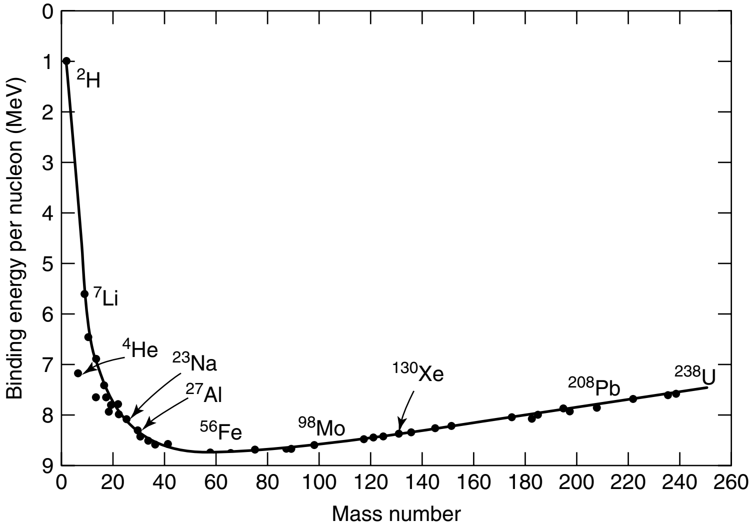

Fig. 29.3 Plot of binding energy per nucleon versus mass number. Reproduced from de Laeter, De Bièvre and Peiser (1992) by permission. © John Wiley & Sons, 1992.

their accurate mass alone (Bristow and Webb, 2003; Bristow, 2006). Assigning molecular formulas unequivocally depends on the mass of the molecule and the diversity of elements that has to be taken into account. For simple organic molecules of the general formula $C_cH_hN_nO_o$, an accuracy of 1 ppm serves this purpose up to about 400 u (Spengler, 2004). In other words, there is no second (reasonable) combination of these elements left that falls within the same mass window of ±0.0004 u. (For an example of the use of high-resolution and accurate mass also refer to Figure 29.23.)

29.2.5
Calculation of Atomic Weights and Molecular Weights

In general, chemistry does not deal with isotopic mass but with *relative atomic mass* A_r or *atomic weight* that is obtained as the average mass of the isotopic mixture of an element:

$$A_r = \frac{\sum_i m_i \times I_i}{\sum_i I_i} \tag{29.2}$$

where m_i is the accurate mass of the isotope i and I_i is its abundance. For molecules, the *relative molecular mass* M_r or *molecular weight* (MW) is obtained analogously.

29.3
Mass Spectrometric Methods

Irrespective of the mass analyzer used, the method depends on the delivery of gaseous ions from an ion source, that is, the formation of ions is a prerequisite for mass spectral analysis of any sample. As MS approaches its 100th anniversary, there is a large variety

Tab. 29.1 Illustrative examples of isotopic mass, isotopic composition, and relative atomic mass (u) of nonradioactive elements. © IUPAC 2001.

of mass spectrometric methods at hand to accomplish this task for almost any sample and almost any analytical task.

Basically, it is much about selecting a suitable *ionization method*, the choice being the key for the outcome of the experiment. Although some mass spectrometers are built in a way to allow for comparatively rapid changes between several ionization methods, others are tailored to fit exactly one type of ion source.

Ionization methods in MS can be grouped in many ways, the most basic being placing them into coordinates of relative softness and state of aggregation in which ionization is effected (Figure 29.4). Under plasma conditions, for example, any inorganic or organic analyte will immediately be dissociated into its constituent atomic species. It is considerably softer to expose sample vapors to energetic electrons, whereby the molecules are ionized. However, owing the amount of energy imparted during this process, the majority of the molecular ions formed may undergo fragmentation. Such ionization methods are termed *hard ionization*. On the other hand, *soft ionization* methods do not impact high levels of energy onto the analyte. Instead, they supply just enough to achieve ionization and eventually a low level of fragmentation of the ionized molecules. The softness of a method increases when vaporization of the sample is not anymore required *before* ionization. Therefore, techniques employing *desorption/ionization*, that is, the direct transition from the condensed phase into the state of isolated ions in the gas phase, are the softest available. Accordingly, the ions detected in MS span from atomic ions on the hard ionization and low-mass side, over small molecules up to large macromolecules by far exceeding 100 000 u.

Fig. 29.4 Classification of common mass spectrometric methods. Although most of these methods, in particular those of organic and bioorganic mass spectrometry, in fact represent ionization methods that can be run on several types of mass analyzers, some require dedicated instrumentation, for example, SIMS as employed for imaging or AMS, which demands a large facility of its own.

29.4 Ionization Processes

There are many processes leading to the formation of charged species. Although some of these are unique to a certain ionization method, others may occur with several ionization methods. The interaction with electrons, for example, plays a role not only in *electron ionization* (EI) but also in *chemical ionization* (CI), *glow discharge* (GD), and less obvious in other technical implementations of ion generation. This section provides an overview of the most relevant ionization processes in MS.

29.4.1 Formation of Positive Radical Ions

29.4.1.1 Electron Ionization

EI (formerly termed *electron impact*) employs the interaction of energetic electrons with gas phase molecules. For *ionization efficiency* reasons, the *primary electrons* are routinely supplied at 70-eV kinetic energy. The energy transferred to the neutral upon collision with the electron forms a short-lived (<1 femtoseconds) electronically excited state. The excited neutral instantaneously emits one of its own electrons, thereby transforming into a positive radical ion, the *molecular ion* (radical ions are marked with • after the charge sign to indicate the unpaired electron).

$$M + e^- \rightarrow M^{+\bullet} + 2e^- \qquad (29.3)$$

If the energy uptake does not exceed the *ionization energy* (IE), that is, the minimum energy required to ionize a neutral in its ground state (generally 7–15 eV), it may subsequently undergo relaxation by either radiative emission or collisions with thermal neutrals (unlikely under the typical operation conditions of an EI ion source).

Multiple ionization can occur, provided sufficient energy has been imparted during interaction with the primary electron:

$$M + e^- \rightarrow M^{2+} + 3e^- \qquad (29.4)$$

$$M + e^- \rightarrow M^{3+\bullet} + 4e^- \qquad (29.5)$$

EI must not necessary lead to molecular ions. If no minimum on the energy hypersurface exists, EI can cause immediate dissociation, the so-called dissociative ionization:

$$M + e^- \rightarrow [M - B]^+ + B^\bullet + 2e^- \qquad (29.6)$$

Another pathway not leading to molecular ions is *ion-pair formation*:

$$M + e^- \rightarrow [M - C]^- + C^+ + e^- \qquad (29.7)$$

$$M + e^- \rightarrow [M - A]^+ + A^- + e^- \qquad (29.8)$$

Note that ion-pair formation simultaneously yields both cations and anions from the analyte molecule. A typical EI mass spectrum is shown in Figure 29.1. (For practical aspects of EI cf. Section 29.6.1.)

29.4.1.2 Photoionization

The absorption of UV light by a neutral can result in electronically excited states that undergo relaxation either by emission of light or by emission of an electron. Thus, the photon in *photoionization* (PI) serves the same purpose as the energetic electron in EI:

$$M + h\upsilon \rightarrow M^* \rightarrow M^{+\bullet} + e^- \qquad (29.9)$$

As with the electron before, the energy absorbed must at least provide the IE of the neutral, that is, lead into a continuum state.

However, ionization with a single photon is technically difficult, because frequency-quadrupled Nd : Yag lasers deliver photons of 266 nm wavelength (4.6 eV) and even ArF excimer lasers just yield 193 nm (6.3 eV), both being well below the IE of most molecules. Fortunately, the absorption of energy has not to be a one-photon process with a highly energetic UV photon. The stepwise accumulation of energy from less energetic photons, that is, *multiphoton ionization* (MUPI) is also feasible.

Nonresonant ionization has rather low cross sections and consequently requires high power densities of the electromagnetic radiation, or results in poor ionization efficiency. Resonant absorption of photons is more effective by orders of magnitude (Wendt, 2002). The most desirable situation is when resonant absorption of the first photon leads to an intermediate state from where absorption of a second photon, preferably but not necessarily of the same wavelength, can promote the molecule into the continuum (1 + 1 process). This approach is termed *resonance-enhanced multiphoton ionization* (REMPI). Proper selection of the laser wavelengths provides compound-selective analysis at extremely low detection limits (Boesl, 2000; Zenobi, Zhan and Voumard, 1996).

It has been shown that typical nanosecond laser pulses can be inferior to picosecond laser pulses, because the latter do not allow the molecules to undergo unwanted relaxation or fragmentation before molecular ion formation, for example, mass spectra of diphenylmercury exhibit a strong molecular ion peak when subpicosecond laser ionization is employed, whereas $M^{+\bullet}$ is completely absent at nanosecond pulse width (Weickhardt, Grun and Grotemeyer, 1998).

29.4.1.3 **Penning Ionization**

Particles occupying long-lived electronically excited states may transfer energy to ground state neutrals. Ionization of the neutral occurs if its IE is lower than the energy received upon interaction with the excited species. This is known as *Penning ionization*(Penning, 1927):

$$M + X^* \rightarrow X + M^{+\bullet} + e^- \qquad (29.10)$$

Penning ionization requires the presence of at least two different species in the gas phase and the chance for at least one collision between those particles within their dwell time in the ionization volume. The species X, for example, a noble gas, is supplied in excess to achieve a reasonable ionization efficiency for the analyte M. The energy to form the excited particles X^* may be delivered by electrons, photons, or an electric discharge. The associative variant of Penning ionization

$$M + X^* \rightarrow MX^{+\bullet} + e^- \qquad (29.11)$$

is also known as *Hornbeck–Molnar* process.

29.4.1.4 **Charge Transfer**

Soft collisions of radical ions with neutrals present another way of ion creation. The neutrals may be ionized by *charge transfer* (CT) if their IE is lower than the *recombination energy* (RE) of the neutral reagent gas X used to deliver the $X^{+\bullet}$ ions. In CT, an electron is removed from the analyte molecule M to neutralize the charge of the *reactant ion* $X^{+\bullet}$:

$$M + X^{+\bullet} \rightarrow M^{+\bullet} + X \qquad (29.12)$$

The overall process is exothermal, that is, the criterion RE > IE needs to be met. In practice, the reactant ions are generated by EI of a large excess of *reagent gas*, which is jointly admitted to the analyte gas.

29.4.1.5 **Field Ionization**

Strong electric fields in the order of $10–25\ \mathrm{V\,nm^{-1}}$ effectively enable the tunneling of an electron from a gaseous molecule into a solid electrode, because the electric field substantially lowers the potential barrier for the electron's escape. The molecule is thereby transformed into its molecular ion, $M^{+\bullet}$, but in contrast to EI this is achieved without significant deposition of internal energy onto the ion. This process is known as *field ionization* (FI). Thus, positive radical ion formation by FI is given as

$$M_{\text{in electric field}} \rightarrow M^{+\bullet} + e^- \qquad (29.13)$$

To achieve reasonable ionization efficiency, high electric field is required, because electron loss may then proceed within about 1 femtosecond. However, a minor degree of ionization is already achieved at significantly lower field strength.

29.4.2
Formation of Positive Ions

29.4.2.1 **Proton Transfer**

All ionization processes discussed so far delivered positive radical ions, because they essentially caused the loss of one electron from the prospective analyte in the gas phase. If a reactant ion can serve as a Brønsted acid, $[BH]^+$, it can act as proton donor, thus yielding a protonated analyte molecule, $[M{+}H]^+$, by exchange of the proton:

$$M + [BH]^+ \rightarrow [M + H]^+ + B \qquad (29.14)$$

The $[BH]^+$ reactant ions are supplied by multistep reactions of primary reactant ions created by EI of the respective reagent gas with neutrals of the same sort. $[M + H]^+$ ion formation is the widest known ionization process in *CI*. Proton transfer must be exothermal to occur, that is, the *proton affinity* (PA) of M must exceed the PA of X. The $[M + H]^+$ ions formed are termed *quasimolecular ions*, because they occur instead of a molecular ion, but are still intimately related to the molecule M. Different from $M^{+\bullet}$ ions, $[M + H]^+$ quasimolecular ions have intact orbitals. They are *even-electron* (or *closed-shell*) ions as opposed to their *odd-electron* (or *open-shell*) radical ion counterparts. Even-electron ions are less prone to fragmentation than radical ions.

29.4.2.2 **Electrophilic Addition**

There are various possibilities of what can happen when an ion encounters a molecule in the gas phase. An elastic collision accompanied by some exchange of kinetic or vibrational energy does not chemically alter the colliding particles. If the collision is soft enough, it can result in adhesion of both particles, that is, *electrophilic addition* in the case of a positive ion (electrophile) attaching to a neutral. This can also be regarded as solvation of the ion in the gas phase. The resulting *ion–neutral complex*, however, bears a charge and becomes accessible for mass analysis:

$$M + X^+ \rightarrow [M + X]^+ \qquad (29.15)$$

As with $[BH]^+$ ions, such X^+ ions are typically provided by multistep reactions of reactant ions initially created by EI of the respective gas. Thus, electrophilic addition presents another CI process.

29.4.2.3 Anion Abstraction

Anion abstraction may also yield a positive analyte ion, the simplest process of anion abstraction being hydride abstraction. Other anionic substituents (A) such as halogenide ions can also be removed:

$$M + X^+ \rightarrow [M - H]^+ + XH \qquad (29.16)$$

$$M + X^+ \rightarrow [M - A]^+ + XA \qquad (29.17)$$

Again, the abstracting species X^+ is provided by multistep reactions of the ionized reagent gas.

29.4.3
Formation of Negative Radical Ions

29.4.3.1 Electron Capture

Thermal electrons and electrons with energies up to a few electronvolts act in much different manner from energetic electrons. Instead of highly exciting the particle by their passage, they become attached to it, creating a negative radical ion:

$$M + e^- \rightarrow M^{-\bullet} \qquad (29.18)$$

Electron capture (EC) is a resonance process requiring that the *electron affinity* (EA) of the neutral is positive, that is, negative ions may occur with analytes containing highly electronegative elements (Harrison, 1992a).

The internal energy of the anion formed is governed by the heat of reaction of the process. Typically, EC yields molecular anions of low internal energy; in other words, it presents rather soft ionization. Nonetheless, the product of AC may spontaneously dissociate if it does not represent an energetic minimum on the energy hypersurface

$$M + e^- \rightarrow [M - B]^- + B^\bullet \qquad (29.19)$$

which is termed *dissociative EC*.

Finally, the EC can also cause ion-pair formation (cf. EI):

$$M + e^- \rightarrow [M - C]^- + C^+ + e^- \qquad (29.20)$$

$$M + e^- \rightarrow [M - A]^+ + A^- + e^- \qquad (29.21)$$

29.4.4
Formation of Negative Ions

29.4.4.1 Nucleophilic Addition

Nucleophilic addition means the attachment of a negative ion (nucleophile) to an electron-deficient neutral. In analogy to electrophilic addition, this may be regarded as solvation of the ion (nucleophile) by the neutral (analyte) in the gas phase:

$$M + A^- \rightarrow [M + A]^- \qquad (29.22)$$

The *negative-ion–neutral complex* formed can be mass-analyzed (Figure 29.5).

29.4.4.2 Cation Abstraction

Cation abstraction can lead to negative analyte ions, the simplest process of cation abstraction being proton abstraction by an anion A^-:

$$M + A^- \rightarrow [M - H]^- + AH \qquad (29.23)$$

Dissociation of acidic molecules can directly result in the corresponding anions:

$$MH \rightarrow [M - H]^- + H^+ \qquad (29.24)$$

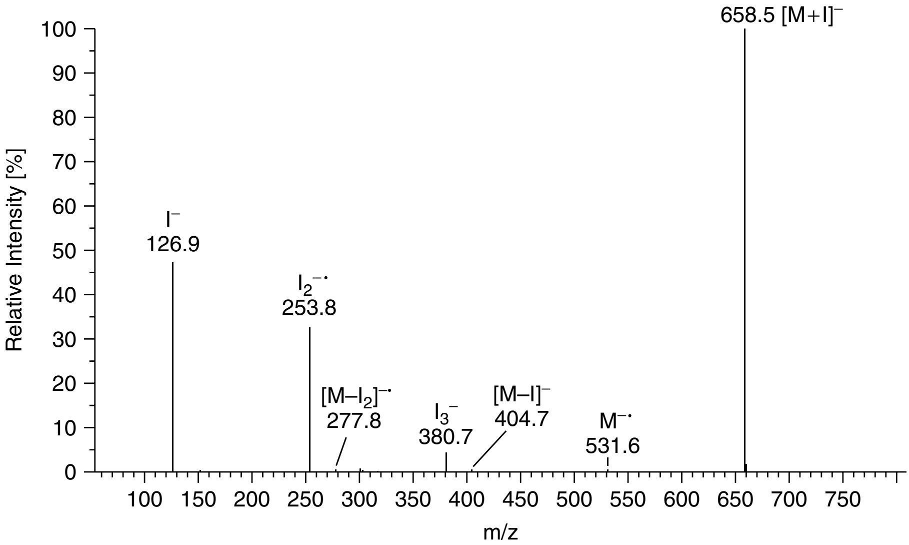

Fig. 29.5 Negative-ion chemical ionization mass spectrum of tetraiodoethene with isobutane reagent gas. The negative molecular ion at *m/z* 531.6 has a relative intensity of only 0.15%, whereas the iodide adduct $[M+I]^-$ at *m/z* 658.5 leads to the base peak of the spectrum. Losses of $I^•$ and I_2 from $M^{-•}$ are also observed. The series of peaks at *m/z* 126.9, 253.8, and 380.7 correspond to traces of iodine present as impurity of tetraiodoethene. The iodine is also ionized by both EC and iodide addition. This spectrum also shows how spectra of two components of a mixture are superimposed. It is not always trivial to tell the corresponding peaks apart. Then, additional experiments such as accurate mass measurements or tandem mass spectrometry are required.

29.5
Isotopic and Elemental Analysis

29.5.1
Thermal Ionization

When a metal salt, metal oxide, or metal placed onto the surface of a rhenium or tungsten filament is heated in vacuum to 400–2300 °C, atomic and eventually molecular ions can be generated by *thermal ionization* (TI), also known as *surface ionization*. Although TI represents another ionization process, and could have been discussed in Section 29.4, it is rather peculiar, because the TI process does not occur with any other ionization method. Basically, its application is limited to *isotope ratio mass spectrometry* (*IR-MS*) of metals, and moreover, TI ion sources are only mounted to dedicated magnetic sector instruments, usually equipped with multicollector systems to measure isotope ratios with highest accuracy (Chapters 3.3.2 and 7.2 in Platzner *et al.*, 1997).

The setup for TI consists of one to three ribbon filaments in close proximity (Figure 29.6). The analyte is supplied on the first filament and evaporated. The neutral atoms or molecules may hit the second filament where they are ionized by electron transfer to (positive ions) or from the bulk metal (anions). With triple filament assemblies, the third filament

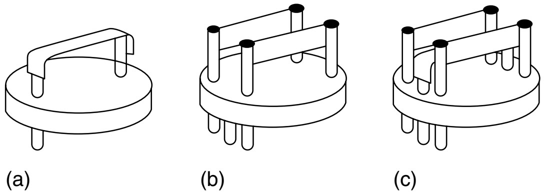

Fig. 29.6 (a) Single filament, (b) double filament, and (c) triple filament assemblies for thermal ionization of metal salts and oxides. Adapted from Platzner *et al.* (1997) p. 27 with permission. © John Wiley & Sons Ltd, 1997.

is normally used to supply a standard in order to sequentially measure unknown and reference under identical ion source conditions. In double and triple filament assemblies, the evaporation and ionization temperatures can be independently controlled. The former is preferably set to low values in order to obtain long-lasting signals and minor isotopic fractionation. The latter is set to high temperature for better ionization efficiency. Consequently, nanograms to micrograms of sample yield signals for hours as evaporation rates are in the order of picograms per second. To avoid frequent breaking of the vacuum, 10–20 filament assemblies are mounted on a carousel-like sample turret.

Blurring of the discrete electronic states of the neutral at high temperature is a key for TI, thereby allowing the Fermi levels of adsorbed neutral and bulk metal to merge. Then, the charge state of the weakly surface-bound particle is purely determined by Fermi statistics, because electrons move freely between the atom and the surface. The Saha–Langmuir equation describes the degree of ionization α^+ expressed as the ratio of ions and neutrals, leaving the surface under the assumption of ideal conditions:

$$\alpha^+ = \frac{N^+}{N^0} = \frac{g^+}{g^0}\exp\left[\frac{e\,(\Phi - IE)}{kT}\right] \tag{29.25}$$

$$= \frac{g^+}{g^0}\exp\left[1.16\times 10^4\frac{(\Phi - IE)}{T}\right] \tag{29.25a}$$

where g^+/g^0 is the ratio of electronic states of the ion and the neutral, Φ is the work function of the filament material, IE is the ionization energy of the atom or molecule to be ionized, and T is the temperature of the filament. As a consequence of this equation, good ion yields are obtained at high temperature with metals of low IE and filament materials with large Φ, which is fulfilled for rhenium ($\Phi_{\mathrm{Re}} = 4.98$ eV, mp = 3180 °C) and tungsten ($\Phi_{\mathrm{W}} = 4.58$ eV, mp = 3410 °C) (Figure 29.7).

Nonmetallic elements with high IE and metal oxides may form negative ions (Kawano and Page, 1983; Kawano, Hidaka and Page, 1983). The degree of ionization α^- is then obtained from the following expression:

$$\alpha^- = \frac{g^+}{g^0}\exp\left[1.16\times 10^4\frac{(EA - \Phi)}{T}\right] \tag{29.26}$$

where EA is the electron affinity of the adsorbed atom.

The low spatial and energetic spread of ions from TI is advantageous for the combination with single-focusing magnetic sector mass analyzers. On the other hand, TI is not suitable for mixture analysis and multielement determinations where ICP-MS is normally employed.

29.5.2
Spark Source

Developed by Dempster in 1935, the spark source provided the first truly multielement and isotopic trace element tool (Koppenaal, 1990). *Spark source mass spectrometry* (SS-MS) is best suited for conducting samples, because it employs a high-voltage electric discharge between two pin-shaped electrodes (about 10 mm long and 1–2 mm in diameter) in vacuum. The electrodes, directly prepared from the solid to be analyzed, need careful cleaning, for example, by etching, before being inserted into the ion source (Chapter 5.2 in de Laeter, 2001, Chapter 2.2 in Becker, 2008) (Figure 29.8).

Nonconducting samples are ground and mixed with high-purity graphite, silver, or gold powder. The mixture is then pressed to yield the electrodes. It is obvious from this procedure that SS-MS is not suited for elemental analysis of small sample amounts; nonetheless, it plays to its strengths for simultaneous analysis of many elements including those present at trace level in alloys, ores, and similar samples.

From the cathode, electrons are emitted by field emission (opposite process to FI), which is possible due to the high local field strengths (10^8–10^9 V m^{-1}) at edges of the microscopically rough surface. The electrons are accelerated toward the anode where they cause evaporation of sample that is then ionized in the gas phase by action of the arriving electrons.

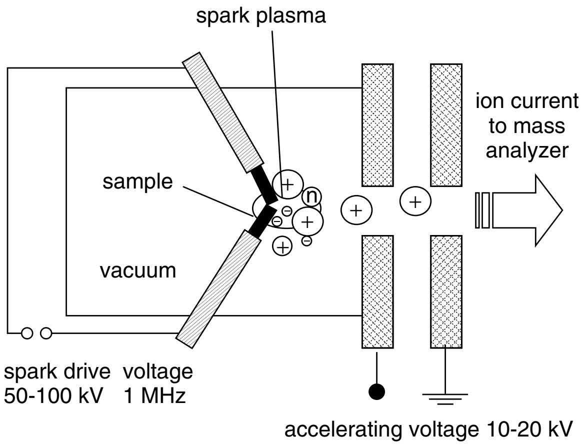

Fig. 29.8 Schematic of a RF spark source. Adapted from Becker (2008) with permission. © John Wiley & Sons Ltd, 2008.

Although operation of a spark source appears simple initially, it is quite demanding. First, it requires a high-voltage supply of several tens of kilovolts, normally at 1 MHz radiofrequency (RF) to achieve uniform ablation of both electrodes. Second, the electrodes need to be carefully adjusted and dynamically readjusted during the measurement (0.1–0.5 mm tip to tip) to maintain a stable ion current. Then, the ions emerge from the discharge with a wide kinetic energy distribution (keV range) that makes a double-focusing mass analyzer mandatory for SS-MS. Still, photoplate detection and subsequent densiometry on a series of exposures, that is, on subsequent spectra acquired for increasing periods of time, are still widespread in SS-MS (Koppenaal, 1990; Verlinden, Gijbels and Adams, 1986). However, multi-ion counting (MIC) systems are promising as they deliver improved sensitivity and precision (Jochum, 1997; Jochum *et al.*, 2001).

29.5.3
Glow Discharge

In 1886, Goldstein was the first to report the formation of positive ions of gases from a *GD* in his so-called channel ray tube (p. 25 in Becker, 2008).

In a GD-MS ion source (Jakubowski *et al.*, 2007; Nelis and Pallosi, 2006; Hoffmann *et al.*, 2005; Stuewer, 1990; King and Harrison, 1990), a discharge current of 1–5 mA is maintained through a dilute argon atmosphere (10^1–10^3 Pa) by applying a DC voltage of 500–1000 V across the ionization volume. The cathode is represented by the solid sample that may be either a disk or a stick and an anode present as the housing and the ion source exit plate (Chapter 5.3 in de Laeter, 2001, Chapter 7.5 in Platzner *et al.*, 1997).

The low-temperature Ar plasma serves as a source of primary ions, excited atoms, and electrons. In the cathode dark space, a region where a large potential drop exists, the positive argon ions are

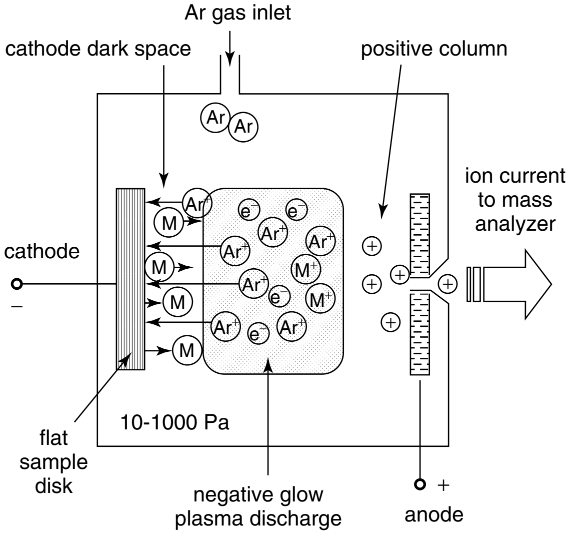

Fig. 29.9 GD ion source with a disk-shaped cathode. Adapted from Becker (2008) with permission. © John Wiley & Sons Ltd, 2008.

accelerated toward the sample cathode (Figure 29.9).

By bombarding the electrode's surface, the impinging ions provide continuous sputtering of neutrals into the gas phase. As the liberated analyte atoms move into the negative-glow region, they may be ionized by either EI or Penning ionization. The negative-glow region emits a bright glow, a phenomenon that led to the construction of the neon lamp. The electron density in the plasma can reach up to 10^{14} cm^{-3} (Penning, 1927) and their energy covers a wide distribution from thermal to energetic. Although their presence in the plasma is less by about a factor of 1000, metastable Ar* atoms are still effective for ionization because they carry 11.55 eV.

Nonconducting samples would rapidly cause the breakdown of the discharge due to electrostatic charging. RF discharges circumvent this problem (Winchester and Payling, 2004). Typically, voltages of 2 kV at RF of 13 MHz are employed.

29.5.4
Inductively Coupled Plasma

Currently, the *inductively coupled plasma* (ICP), developed by Houk *et al.* (1980), probably presents the most frequently employed method of element MS (Chapter 4 in de Laeter, 2001, Chapter 5 in Becker, 2008, Chapter 7.3 in Platzner *et al.*, 1997). Its widespread use is due to a highly versatile sampling mode that, in addition, is comparatively simple and robust because atomization and ionization are achieved in an argon plasma at atmospheric pressure. The ICP provides high ionization efficiency for elements of low IE (0.98 for 7 eV). Although these values drastically drop (0.01 for 13 eV), it is still sufficient to access elements such as P and even Cl.

The plasma is maintained by coupling electric energy (1–2 kW) from a surrounding RF (27 MHz) coil into the gas. The ion motion induced by the magnetic field causes the gas phase to heat up until it forms a continuously flowing plasma of about 8000 K at the center. The analyte is introduced axially into this plasma by a nebulizer that dissipates solutions and suspensions or by admitting gaseous samples.

The plasma torch consists of a coaxially aligned set of three quartz tubes, the outer of which is about 20 mm in diameter and is surrounded by the water-cooled RF coil. An argon stream of 12–15 l min^{-1} is used to cool the walls. The middle tube supplies a stream of Ar (1–2 l min^{-1}) as nebulizer gas to assist the formation of droplets at a size of tens of micrometers from the sample aerosol that is admitted by another gentle Ar stream from the 1–2 mm i.d. center tube (Figure 29.10).

The ions are transferred into the mass analyzer via a differentially pumped interface. A small portion of the plasma enters the first pumping stage through a

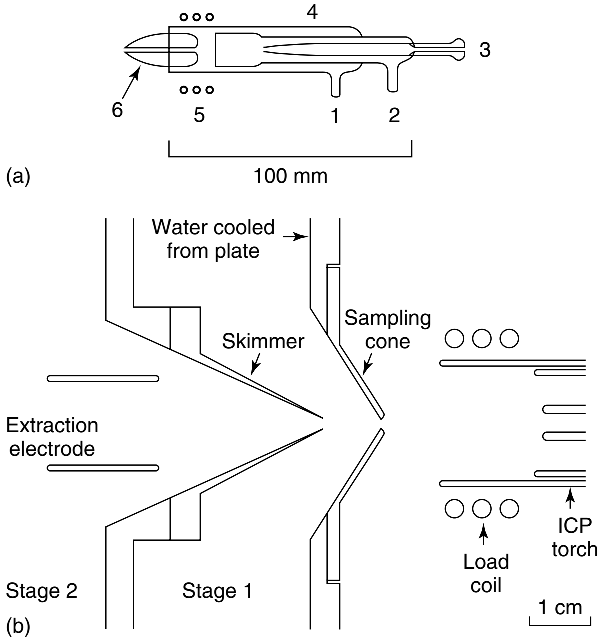

Fig. 29.10 Schematic diagram of (a) an ICP torch where 1 and 2 are inlets for argon sheath and nebulizer gas, 3 inlet for the sample, 4 the outer quartz tube of the torch, 5 the RF coil, and 6 the plasma. (b) An ion extraction interface for ICP-MS. Ions arrive from the right, a small portion is transmitted through the water-cooled sampling cone into the first pumping stage (rotary pump), the center of the free-jet expansion is then transmitted through the second skimmer cone, behind which it is guided by electric potentials through the second pumping stage (turbo pump) into the mass analyzer. Fig. 29.11 Partial ICP mass spectrum of a radioactive waste solution in the range m/z 180–250 as obtained in low-resolution mode. The insert showing the m/z 235 range is taken from a spectrum as obtained from the same magnetic sector instrument when operated in high-resolution mode at $R = 3000$. Then, the signals due to ^{187}ReO$_3^+$ and ^{235}U$^+$ can easily be distinguished. Adapted from Becker and Dietze (1999) with permission. © The Royal Society of Chemistry, 1999.

hole in the water-cooled sampling cone. Application of suitable electric potentials guides the ions through the entrance of the skimmer, whereas neutrals are pumped off the supersonic expansion in this region. The first implementation of ICP-MS used a quadrupole analyzer due to its acceptance of moderate vacuum conditions (Houk *et al.*, 1980). In between, magnetic sector (Figure 29.11) (Becker and Dietze, 1999), time of flight (TOF), and Fourier-transform ion cyclotron resonance (FT-ICR) mass analyzer are also employed.

To further complete the sampling repertoire, a gas stream may be employed to take up neutrals generated by *laser ablation* (LA). LA-ICP-MS can be used for sampling from solid surfaces of bulk material or alternatively for imaging of element distributions in the upper layers of tissues and similar samples (Figure 29.12). Thus, LA-ICP-MS is being used in biomedical research (Guenther and Hattendorf, 2005; Chery *et al.*, 2006; Becker *et al.*, 2007).

Another advantage of the acceptance of liquid introduction is the coupling of LC and gel electrophoresis to ICP instruments to allow for *element speciation.* This way not only the presence of an element in a sample can be detected but also the assignment to molecular species becomes feasible. This is relevant for the identification of non-C,H,N,O elements in proteins, for example (Ray *et al.*, 2004).

29.5.5
Accelerator Mass Spectrometry

Accelerator mass spectrometry (*AMS*) presents an extremely sensitive technique for isotopic analysis (Tuniz *et al.*, 1998). AMS allows to measure isotope ratios for some elements to a level of 1 in 10^{15}, which is by a factor of 10^5 lower than in other mass spectrometers. Moreover, this can be achieved for samples of about 1 mg, that is, only one million atoms of the isotope of interest are present, making it ideal for isotope ratio measurements of low-abundant isotopes, especially those having too long half-lives for counting radioactive decay from small sample amounts such as carbon-14.

The methodology of AMS differs greatly from all other approaches to the analysis of atomic mass. The main characteristic of AMS lies in the energies to which the ions are accelerated. Although other mass analyzers deal with ions having 10 eV–10 keV, in AMS they are at several megaelectronvolts. To achieve this, negative ions are created in an ion source and are mass-analyzed before entering a linear *Van de Graaff accelerator* or a *tandem accelerator*. In a tandem accelerator, negative ions are attracted by positive voltage toward the so-called high-voltage terminal at the center of the vessel. By passing the beam through a thin carbon foil (foil stripper) or a gas collision cell (gas stripper), electrons are stripped off the anion, thereby converting it to a positive ion. The atomic cations are then pushed away from the high-voltage terminal toward the exit of the accelerator. These are then mass-analyzed in a unit that basically represents a large magnetic sector instrument. The typical AMS setup requires some hundred square meters (Figure 29.13).

The higher energies enable ambiguities in the identification of atomic ions to be avoided, because molecular species are completely destroyed at the stage of the stripper. Furthermore, the selection

In total, the sample is ionized, and ions are preselected in a magnetic sector, accelerated to mega electronvolt energies, charge-inversed in the stripper, separated according to their momentum, charge, and energy, and finally counted individually (Tuniz *et al.*, 1998).

of a suitable high charge state, characteristic of the isotope of interest, permits unequivocal identification, for example, ^{14}C, ^{26}Al, and ^{129}I are already separated from isobaric ^{14}N, ^{26}Mg, and ^{129}Xe due to the instability of the respective negative ions.

Carbon-14 dating was the application that gave birth to AMS (Nelson, Korteling and Stott, 1977; Bennett *et al.*, 1977). Today, AMS is also employed for the determination of isotopes such as ^{10}B, ^{26}Al, ^{36}Cl, ^{41}Ca, ^{129}I, and others including stable isotopes. This versatility has led to applications of AMS in many areas of research including life sciences, geosciences, archeology, and extraterrestrial materials (Brown, Dingley and Turteltaub, 2005; Brown, Tompkins and White, 2006; Ikeda, 2005; Kutschera, 2005).

29.6
Ionization of Gaseous Molecules in Vacuum

All classical ionization methods of organic MS imply ionization in the diluted gas phase. They are applied for small molecule analysis ($M < 800$ u), provided the analyte does not contain too many heteroatoms. Molecules with more than a few oxygen, nitrogen, or sulfur atoms (highly functionalized molecules) are normally very polar – a property preventing their evaporation without prior thermal decomposition. Furthermore, molecular ions of such species often undergo facile fragmentation making them difficult to recognize in the mass spectrum. Thus, the important assignment of molecular mass is rendered impossible and the structure elucidation based

Tab. 29.2 Methods of sample evaporation.

Inlet system	Principle of operation	Cases where applicable	Limitations
Reservoir inlet (also termed *reference inlet, gas inlet*)	Injection into a heated reservoir and admission to the ion source via a needle valve. Inlet is emptied by evacuation	Gases and liquids	Risk of thermal decomposition of the sample. Memory from previous samples
Direct probe (also termed *direct insertion probe or direct inlet system*)	Evaporation from a small vial placed onto the temperature-controlled tip of a probe which is inserted through a vacuum lock	High-boiling liquids, waxes, solids	Risk of thermal decomposition of the sample

on fragment ions alone normally fails. Table 29.2 compares methods of sample evaporation.

29.6.1
Electron Ionization

EI, formerly termed *electron impact* (*EI*), employs the interaction of energetic electrons with gas phase molecules. The electrons are generated by thermionic emission from a heated tungsten or rhenium filament. In EI, ions isolated in the gas phase should be formed to avoid ion–molecule reactions. Therefore, the pressure in the ionization volume of an EI ion source is maintained in the range of 10^{-5}–10^{-6} mbar so that their mean free path (about 1 m) is by far longer than the average distance traveled within the ionization zone of ion source (in the order of 1 mm). Their ion source dwell time is about 1 microsecond due to the extracting electric field accelerating them from the zone of creation to generate a continuous ion beam into the mass analyzer (Figure 29.14).

Quantitative energy transfer is required for ionization to occur, when an electron possessing energy just equal to IE collides with a neutral. Such an event is of low probability and, therefore, the *ionization efficiency* is then close to zero. However, a slight increase in electron energy brings about a steady increase in ionization efficiency. Every molecule has an ionization efficiency curve of its own (Figure 29.15). The overall efficiency of EI depends on the intrinsic properties of the ionization process as well as on the ionization cross section of the analyte. Fortunately, the curves of ionization cross section versus electron energy are very similar in shape, exhibiting a maximum at electron energies around 70 eV. In addition, the plateau of the ionization efficiency curve around

70 eV makes variations in electron energy negligible; in practice, EI works equally well at 60–80 eV. This assures better reproducibility of spectra and, therefore, allows comparison of spectra obtained from different mass spectrometers or from mass spectral databases. Therefore, EI spectra are almost exclusively acquired at 70 eV.

Once formed, the molecular ions "experience a rich life" during this short time span (Figure 29.16).

It takes less than 10^{-15} seconds for an electron of 70-eV kinetic energy to

pass through a molecule. Vibrations, the fastest internal motions of a molecule, are slower by at least two orders of magnitude, for example, a C–H stretching vibration takes roughly 1.1×10^{-14} seconds per cycle. Thus, the electronic motion and the nuclear motion are in fact separated, that is, the *Born–Oppenheimer approximation* is valid (Born and Oppenheimer, 1927; Seiler, 1969). Now, the *Franck–Condon principle* states that the probability for an electronic transition is highest where the electronic wave functions of both ground state and ionized state have their maxima. Combining these tenets explains the occurrence of the so-called *vertical transitions* (Franck, 1925; Condon, 1926). (Also cf. Section 29.4.1.1 for processes under EI conditions.) Although there is a wealth of chemical reactions, all of them are strictly unimolecular, because the mean free paths are long enough to prevent bimolecular interactions within the lifetime of the ions. Ions of very low internal energy reach the detector and are thus termed *stable ions* (within the below timescale); those that have life times long enough to leave the ion source but decompose during their flight through the analyzer are termed *metastable ions*, and those that fragment inside the ion source are called *unstable ions*.

The kinetics of these reactions are commonly described by the *quasi-equilibrium theory* (QET) (Wahrhaftig, 1986; Märk, 1986; Rosenstock and Krauss, 1963; Wahrhaftig, 1959).

Ions with moderate internal energy undergo decomposition reactions along well-defined pathways, leading to *fragment ions* having structures that are still closely related to the intact molecule. Interpretation of EI spectra following these routes and some well-established rules can therefore lead to the identification of a compound (McLafferty and Turecek, 1993, Chapter 6 in Gross, 2004). A sample EI spectrum of the over-the-counter drug ibuprofen elucidates the basic principle (Figure 29.1).

29.6.2
Chemical Ionization

There are various possibilities of what can happen when an ion encounters a molecule in the gas phase. An elastic collision accompanied by some exchange of kinetic or vibrational energy does not chemically alter the colliding particles. However, if the collision is soft enough it can result in adhesion of both particles or in exchange of charge via mutual transfer of either an electron or some (small) ions such as a proton. All these processes contribute to the manifold approaches to *CI*.

To enable bimolecular processes within the microsecond timeframe, the pressure inside the ion source has to be substantially raised to 10^{-4}–10^{-3} mbar by the introduction of a reagent gas that is then present in more than 1000-fold excess over the analyte. The analyte molecules undergo in the order of 50 collisions (as opposed to none in EI) and, thus, become thermalized and accessible to ion–molecule reactions. To avoid excessive leakage into the remaining mass spectrometer, the ionization volume of a CI ion source has only small holes for the entrance and exit of electrons, reagent gas, sample vapor, and ions produced (Figure 29.17). Sufficient pumping capacity is required at the ion source housing to maintain high vacuum conditions.

Nowadays, there are numerous variations of *CI* introduced in the mid-1960s (Field and Munson, 1965; Harrison, 1992b). *Positive-ion chemical ionization* (PICI or PCI) (Harrison, 1992b; Munson, 2000) employs either proton transfer (Section 29.4.2.1), electrophilic addition (Section 29.4.2.2), and anion abstraction (Section 29.4.2.3) or CT (Section 29.4.1.4) to generate analyte ions. The reagent gases methane and isobutane are preferred for $[M + H]^+$ ion formation, ammonia tends to yield $[M + NH_4]^+$ by electrophilic addition, and gases such as benzene, carbondisulfide, or noble gases serve for the production of $M^{+\bullet}$ ions by CT (Allgood, Ma and Munson, 1991; Hsu and Qian, 1993; Roussis, 1999).

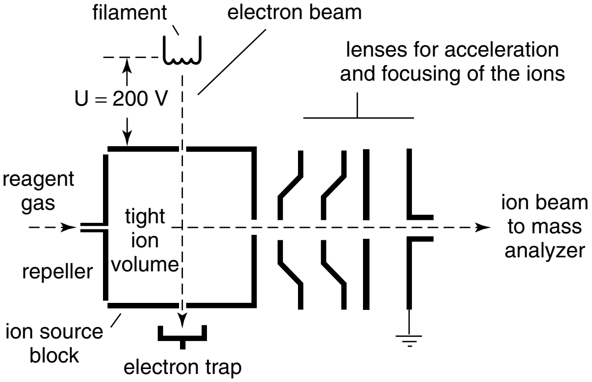

Fig. 29.17 A CI ion source can be readily obtained by replacing the ionization volume of an EI ion source with a tighter one. Many mass spectrometers have EI/CI combination ion sources switching between these methods by pushing a cylinderlike insert into the EI volume in order to close its vents (cf. Figure 29.14). Adapted with permission from Schröder (1991). © Springer-Verlag, 1991.

Negative-ion chemical ionization (NICI or NCI) (von Ardenne, Steinfelder and Tümmler, 1971; Dillard, 1973) makes use of cation abstraction (Section 29.4.4.2), nucleophilic addition (Section 29.4.4.1 and Figure 29.5), or EC (Section 29.4.3.1), the latter being no CI in the strict sense, because the reagent gas (often isobutane) solely moderates the electrons to thermal energy instead of involving any reaction (Knighton and Grimsrud, 1995). Alternatively, the electrons may be delivered from an electron monochromator (Laramée *et al.*, 1996).

The goal of CI is to generate quasimolecular ions or molecular ions of low internal energy in order to reduce the degree of fragmentation. The corresponding ions generally are well recognized in CI spectra of both polarities while the moderate fragmentation still assists structure elucidation of unknowns. It is common to combine the information obtained from both EI and CI spectra (Figure 29.18), or from positive-ion plus negative-ion CI spectra to improve the reliability of the mass spectral analysis.

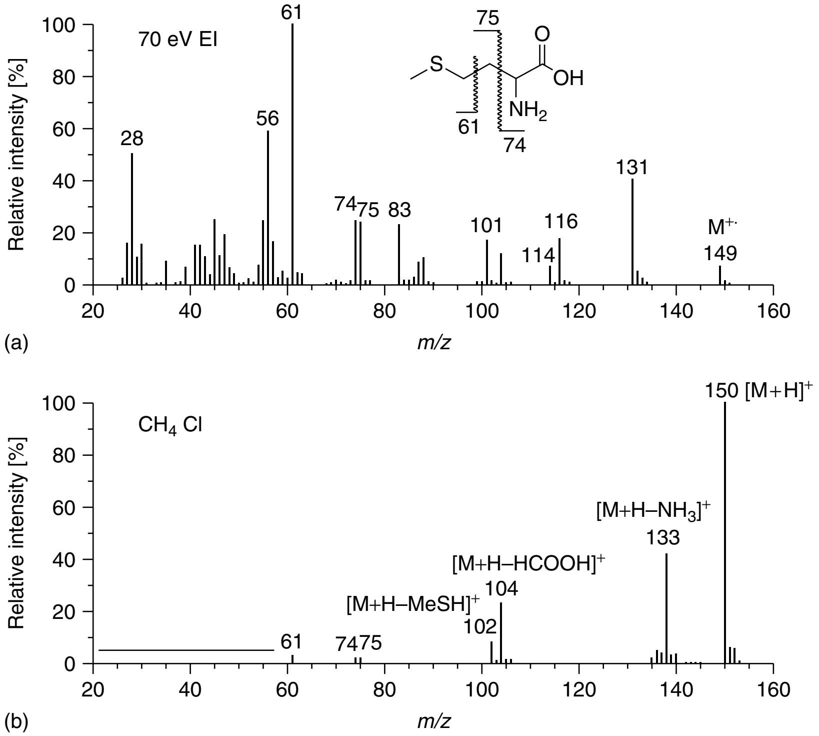

Fig. 29.18 Comparison of (a) 70-eV EI mass spectrum and (b) methane reagent gas CI mass spectrum of the amino acid methionine. The range up to *m*/*z* 60 has been excluded from the CI spectrum, because it is dominated by peaks due to the reagent gas. The reduction in fragmentation as effected by the generation of the closed-shell quasimolecular ions, $[M + H]^+$, in CI is obvious. This also results in easier identification of the sulfur isotopic pattern. Reprinted from Gross (2004) with permission. © Springer-Verlag, 2004.

29.6.3
Field Ionization

In FI, molecular ions, $M^{+\bullet}$, are softly created from gas phase neutrals by action of strong electric fields causing tunneling of an electron from a gaseous molecule into a solid electrode, the field anode (Section 29.4.1.5) (Gomer and Inghram, 1955; Beckey, 1962; Beckey, 1971; Lattimer and Schulten, 1989; Gomer, 1994). Although some micrometer-thin metal wires were employed as electrodes in pioneering work on FI, the use of activated emitters – occasionally specially optimized for FI usage – has become standard in FI-MS. The process of *emitter activation* transforms a tungsten wire of 5–13 μm in diameter into a rather fragile object resembling a hairy caterpillar species (Beckey, Krone and Röllgen, 1968; Beckey, Hilt and Schulten, 1973; Okuyama *et al.*, 1977; Rabrenovic, Ast and Kramer, 1981). These *whiskers* grown on the central wire cause an enormous increase in the electric field strength at their tips as compared to bare wires, because the radii of curvature are drastically reduced. Thus, the activated emitter provides a large number of high electric field sites for FI to occur.

The setup of an FI ion source comprises the field emitter opposed to a counter electrode set to a potential of 10–12 kV negative relative to the emitter (Figure 29.19). The emitter can be resistively heated up to about 1000 °C by passing a current of 50–90 mA through it in order to bake off any condensed sample residues between subsequent measurements. During operation, the resistive heating is normally switched off or set to low levels. The sample vapor can be introduced by any of the means listed in Table 29.2.

As long as the process of sample evaporation is not limiting, FI spectra are mainly characterized by the molecular ion peak of the analyte, eventually accompanied by few generally low-abundant fragment ions (Figure 29.20).

Owing to some degree of surface adhesion in FI, there are two accompanying processes influencing the spectra. On one side, ions formed may encounter a second step of ionization, leading to M^{2+} ions. On the other side, bimolecular processes can cause the formation of $[M+H]^+$ ions analogous to the generation of protonated

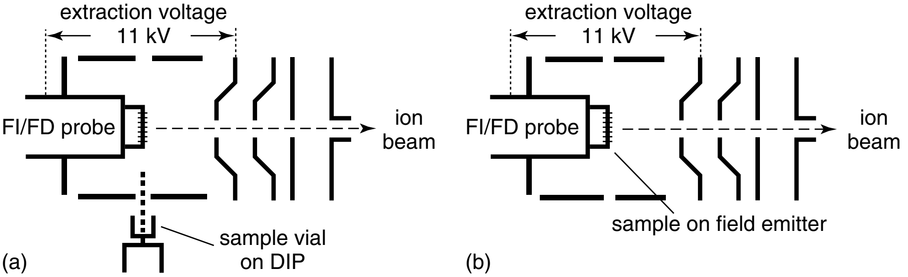

Fig. 29.19 Schematic drawings of (a) FI and (b) FD ion sources. Field ionization has lead to the development of *field desorption* (FD) where the sample is directly placed onto the emitter surface from dilute sample solution by evaporation of the solvent (Section 29.7.1). reagent gas molecules in CI (Schulten and Beckey, 1974). Although doubly charged ions are easily recognized in mass spectra by their spacing of isotopic peaks (cf. Section 29.2.3 and Figure 29.2), the partial protonation can lead to misinterpretation of isotopic patterns.

29.7
Desorption/Ionization

When the generation of gas phase ions can be accomplished by combining both evaporation and ionization into a single process, thermal decomposition before ionization can be avoided for the most part. Although CI and FI already belong to the so-called soft ionization methods, these do not possess this key property, and many of their applications have soon been replaced by *desorption/ionization* methods when they became commercially available. In contrast to EI, CI, and FI, desorption/ionization methods handle ionic analytes very well. In fact, ionic analytes are even beneficial, because they only require transfer into the gas phase, while the actual ionization step is not necessary anymore.

The numerous types of ions formed by the various desorption/ionization methods can be conveniently organized by their relevance for analytes of given polarity and charge (Table 29.3). FD (Section 29.7.1) covers the table's left column only, while LSIMS and FAB (Section 29.7.2) as well as LDI (Section 29.7.3) apply to the whole table with a compound-dependent high-mass limit of about 2000–5000 u. Finally, MALDI (Section 29.7.4) can access the whole polarity–analyte mass range, although it is not ideally suited for unpolar analytes and molecules below 500 u.

29.7.1
Field Desorption

FI has been further developed to *field desorption* (FD) where the sample is directly placed onto the emitter surface

from dilute sample solution by a microliter syringe. After evaporation of the solvent, the emitter is inserted into the ion source. Therefore, a FD ion source is basically identical to an FI ion source (Figure 29.19). In FD, the analyte can be field ionized (the mechanism of ion creation) while still adsorbed to the surface or while just being on the leave. This leads to a significant reduction in thermal decomposition of the analyte and thereby allows for the analysis of highly polar molecules up to about m/z 2000 (Beckey, 1977; Wood, 1982; Prókai, 1990a; Prókai, 1990b). To achieve sufficient surface mobility, the emitter is resistively heated by ramping a current at 1–16 mA min^{-1} up to 40–60 mA during the measurement. High *emitter heating currents* (EHC) are employed to remove residual sample. Analytes of low polarity are even successfully analyzed up to higher molecular weights, for example, polystyrenes are accessible by FD up to m/z 10.000 (Lattimer, 2001).

The type of ions produced by FD depends on the analyte's polarity. Compounds of low polarity yield $M^{+\bullet}$ ions, medium polarity molecules are transformed into either $M^{+\bullet}$ ions or quasimolecular ions such as $[M+H]^+$ or $[M+\text{alkali}]^+$, and finally, highly polar compounds only form quasimolecular ions. Ionic analytes (cation C^+ and anion A^-) are desorbed from the surface without prior FI. C^+ is then detected as the most intensive peak, followed by $[C_nA_{n-1}]^+$ cluster ions. Often, nonionic analytes also form cluster ions, for example, $[2M+H]^+$, $[2M+\text{alkali}]^+$, to some degree (Figure 29.21).

Negative-ion FD is a rare exception (Daehling *et al.*, 1982; Dähling *et al.*, 1983), because emission of electrons,

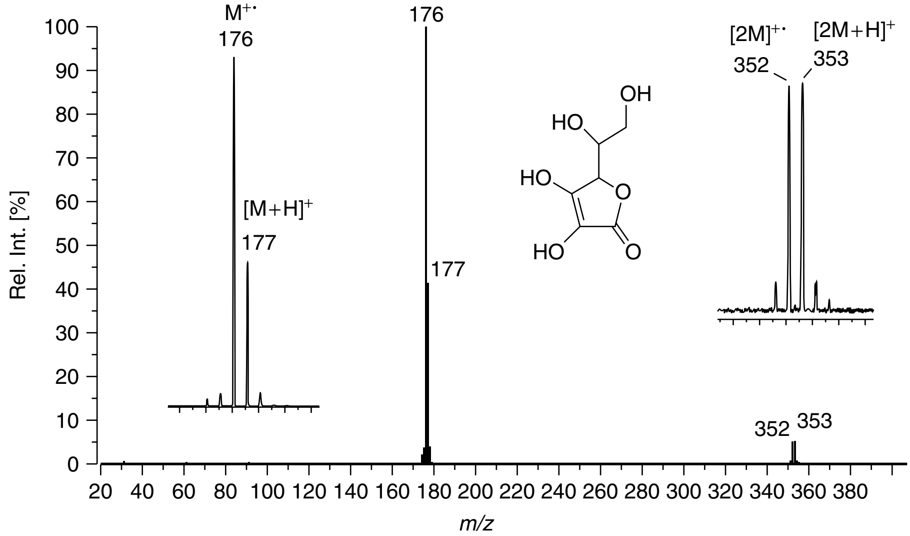

Fig. 29.21 FD mass spectrum of ascorbic acid showing $M^{+\bullet}$ and concomitant $[M+H]^+$ ions. This can be inferred from the overgrown isotopic pattern that cannot be due to $C_6H_8O_6$ alone, because then $[M+1]$ should only exhibit 6.6% relative to $M^{+\bullet}$ instead of the observed 41%. The cluster ion signal shows this phenomenon even more obviously.

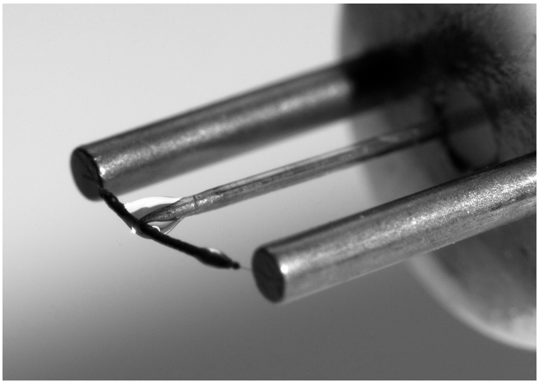

Fig. 29.22 The basic, nonetheless crucial, difference between LIFDI and standard FI or FD is the addition of the capillary. In LIFDI, the field emitter is loaded with analyte solution via this capillary positioned close to the activated area. The liquid spreads over the entire length and the solvent evaporates in vacuum. The thin central tungsten wire connecting this section to the posts is barely visible.

detrimental for the emitter, occurs from activated emitters before analyte ion formation.

The advent of *liquid injection field desorption/ionization* (LIFDI) gave new impetus for the use of FD. In LIFDI, the analyte solution (0.1–0.2 mg ml^{-1}) is transferred onto the emitter inside the ion source by a fused silica capillary (10–75 µm i.d.) (Figure 29.22). In this manner, LIFDI (i) offers inert conditions (Linden, 2004; Gross *et al.*, 2006), (ii) speeds up the measurement process by reducing the number of tuning cycles, and (iii) even admits continuous-flow applications (Schaub *et al.*, 2004). The combination of LIFDI with FT-ICR instruments is gaining importance in industrial analysis, for example, of nonpolar compounds in petroleum products (Figure 29.23) (Schaub *et al.*, 2005).

29.7.2
Fast Atom Bombardment and Liquid Secondary Ion Mass Spectrometry

Energetic particles impacting onto a surface are capable of both sputtering ions as well as neutrals into the selvedge region and ionization of those gas phase neutrals (Figure 29.24). The development of the title methods started with the introduction of ion beams for the production of secondary ions from inorganic surfaces and hence the name *secondary-ion mass spectrometry* (SIMS)(Benninghoven and Kirchner, 1963). Nonconduction materials build up electric charges that prevent further useful ion production by Coulombic repulsion. Thus, primary ion beams were replaced by atom beams (*fast atom bombardment*, FAB) (Devienne, 1967; Barber, Vickerman and Wolstenholme, 1980) that can be obtained by passing rare gas ions through a collision cell where they are neutralized while their kinetic energy and direction are basically retained (Figure 29.25).

The introduction of a *liquid matrix* to dissolve the analyte made FAB a method for the soft ionization of highly polar and eventually large organic or bioorganic molecules (Morris *et al.*, 1981; Barber *et al.*, 1982). In addition, the matrix allowed to employ primary ion beams again, because it circumvented electrostatic charging of the target, thereby giving rise to *liquid secondary-ion mass spectrometry* (LSIMS) (Benninghoven, 1983). FAB and LSIMS work equally well for the

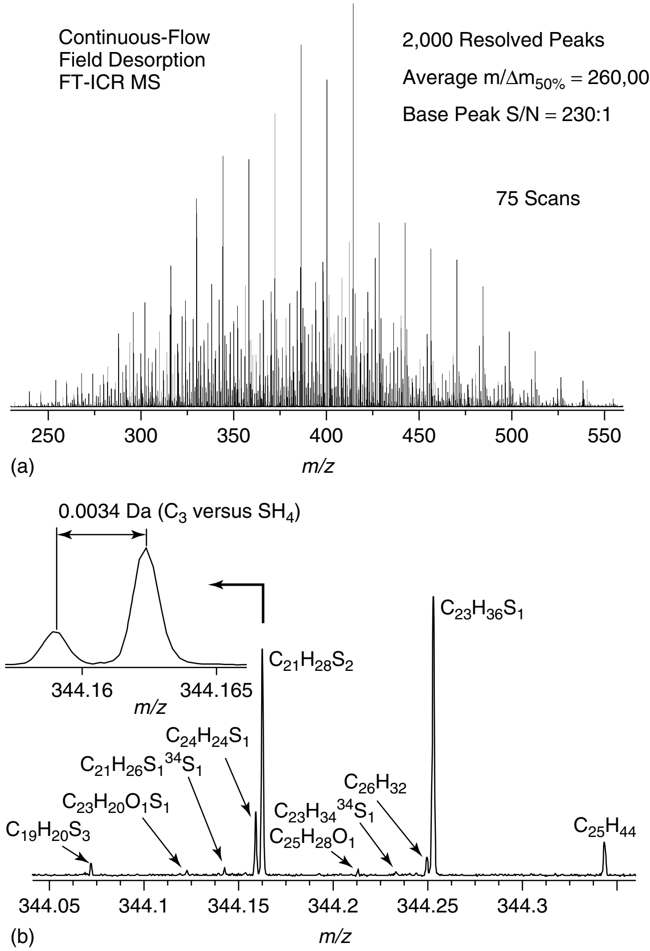

Fig. 29.23 (a) Continuous-flow FD-FT-ICR mass spectrum of a refinery process stream sample; the spectrum is the average of 75 single spectra accumulated during 1 hour. (b) Mass scale expansion at nominal m/z 344 from the broadband mass spectrum. The resolution of the 3.4×10^{-3} u distant C_3 versus SH_4 duplet can be observed at m/z 344.25 and separately in the inset at m/z 344.16. whole range of sample polarities and for negative-ion and positive-ion generation (Chapter 9 in Gross (2004) and Table 29.3).

The use of a liquid matrix, for example, glycerol, thioglycerol, 3-nitrobenzylalcohol, 2-nitrophenyloctylether, is key to the abilities of FAB and LSIMS. The matrix absorbs the primary energy, avoids intermolecular interactions of analyte molecules by dissolution, serves as a source of protons for $[M + H]^+$ ion formation by its natural acidity, and mediates the ionization in solution by other

Fig. 29.25 Schematic representation of a FAB gun. The supply of neutral gas also serves as a collision chamber for charge exchange to transform the energetic primary ions generated by EI into a beam of fast neutrals hitting the sample solution on the target. In a FAB ion source, the target takes the same position as the FI/FD probe in Figure 29.19 or the reagent gas inlet in Figure 29.17, respectively; further changes as compared the previously shown ion sources are not required. Therefore, EI/CI/FAB combination ion sources are common. Ion volumes exchangeable through a vacuum lock can reduce ion source contamination.

ionic species, either present as traces such as the ubiquitous alkali ions or by deliberately added ones such as organic acids, salts, and so on (De Pauw, Agnello and Derwa, 1986). Unfortunately, evaporation of the matrix accelerates ion source contamination and limits the time span for sampling of spectra. In addition, abundant ions are produced from the matrix, delivering a strong background of peaks at every m/z with $[n\text{Ma} + \text{H}]^+$ or $[n\text{Ma} - \text{H}]^-$ matrix cluster ions typically dominating those spectra. Therefore to be identified, the analyte ions need to yield strong signals clearly distinguished from that background. Continuous-flow FAB (CF-FAB) (Caprioli, Fan and Cottrell, 1986) and frit-FAB (Ito *et al.*, 1985) not only improve the signal-to-background ratio but also present a means for LC coupling and real-time monitoring of physiological processes by FAB (Caprioli, 1990).

Although still in use, FAB and LSIMS have widely been replaced by more recent desorption/ionization and related methods (see below). One of the advantages of FAB and LSIMS is their ability to actively generate ions from neutrals in unpolar and aprotic matrix solutions, at cryogenic temperatures even from typical organic chemistry solvents (LT-FAB) (Wang *et al.*, 1998; Gross, 1998).

29.7.3
Laser Desorption/Ionization

Different from FAB and LSIMS, *laser desorption/ionization* (LDI) does not provide a continuous beam of ions. Owing to the pulsed nature of a laser, ions are generated in extremely short bursts, the duration of which being slightly longer than the pulse width of the laser. Typically, nitrogen lasers, that is, UV lasers at a wavelength of 337 nm delivering 3 nanosecond pulses are employed. Laser and optics are normally located on top of the ion source housing from where the light is guided onto a sample plate (target) through a quartz window (Figure 29.26). The energy provided by the laser is then absorbed by a (normally solid) layer of the analyte where it causes evaporation

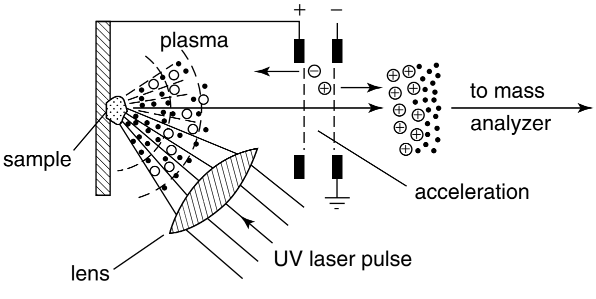

Fig. 29.26 Schematic of an ion source for laser desorption/ionization. The solid sample layer is irradiated with a laser pulse in vacuum. Ions created during this pulse and in the immediate aftermath are extracted from the laser-generated plume and accelerated into a (time-of-flight) mass analyzer. Reproduced from Mamyrin (1994) with permission. © Elsevier Science Publishers, 1994.

and ionization in analogy to the effects of impacting particles as described in Section 29.7.2 (Fenner and Daly, 1966; Vastola and Pirone, 1968; Vastola, Mumma and Pirone, 1970; Posthumus *et al.*, 1978). In addition, nonresonant MUPI in the gas phase can occur (cf. Section 29.4.1.2).

The direct transfer of energy to the analyte, however, creates a significant portion of ions excited well above their dissociation threshold. Therefore, LDI is not as soft as FAB or especially FD. Nonetheless, the fact that LDI is an "energy-sudden" method can compensate for those levels of internal energy, because dissociation kinetics is slower by some orders of magnitude than ion formation (cf. time scale of EI, Figure 29.16).

Stable, UV-absorbing molecules such as fullerenes, polycyclic aromatic hydrocarbons (PAHs), or low-mass organic or inorganic salts are easily analyzed by LDI. In fact, LDI-MS has played an important role in the discovery of the fullerenes (Figure 29.27) (Kroto, 1997).

Although still rather soft and well applicable to analytes up to about *m*/*z* 2000, LDI has its drawbacks in (i) the necessity of an UV chromophore in the analyte molecules and (ii) the conservation of intermolecular forces within the analyte layer that together pose limits upon the application of LDI to highly polar compounds such as oligosaccharides, peptides, and proteins (Posthumus *et al.*, 1978; McCrery, Ledford and Gross, 1982; Cotter, 1987).

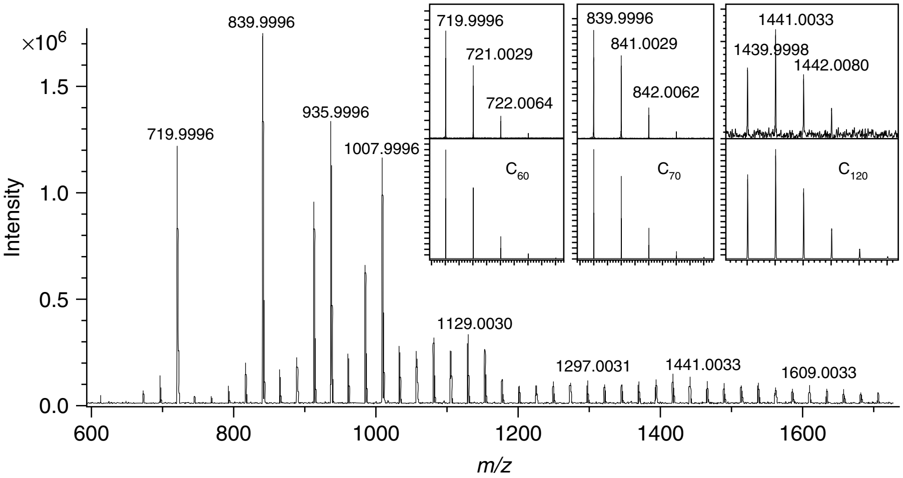

Fig. 29.27 Positive-ion LDI mass spectrum of a fullerene soot synthesized by the Krätschmer–Huffman method (Krätschmer *et al.*, 1990). The spectrum was obtained on a Fourier-transform ion cyclotron resonance (FT-ICR) mass spectrometer; hence, the resolution is 175.000 (1.75×10^5) at *m*/*z* 840, that is, almost by a factor of 1000 higher than on early time-of-flight instruments as used for the discovery of C_{60} and larger fullerenes (Kroto, 1997) The insets show expanded views of the $M^{+\bullet}$ ions for C_{60}, C_{70}, and C_{120} (upper traces) together with the corresponding calculated isotopic patterns. Note that the accurate masses are lower than the nominal values by the mass of an electron, while the difference in mass of 1.0033 u between ^{12}C and ^{13}C can be recognized from the mass increment of the first and second isotopic peaks.

29.7.4
Matrix-Assisted Laser Desorption/Ionization

Tanaka's approach to establish a matrix in LDI was the use of glycerol with an admixture of ultrafine cobalt powder (particle size about 30 nm) serving to transform the UV-transparent liquid into a UV-absorbing medium (Tanaka *et al.*, 1988; Tanaka, 2003) However, the restricted variability of this matrix limited its use to proteins and polar synthetic polymers, and moreover, the poisonous cobalt prevented its adoption as a routine technique.

The other approach, introduced by Hillenkamp and Karas, involved a crystalline organic matrix and started a revolution in terms of what kind of analytes became accessible by MS. Thus, *matrix-assisted laser desorption/ionization* (*MALDI*) with its capability to analyze intact proteins as large as antibodies (150.000 u) meant that MS had really entered the realms of biology and medicine (Figure 29.28)

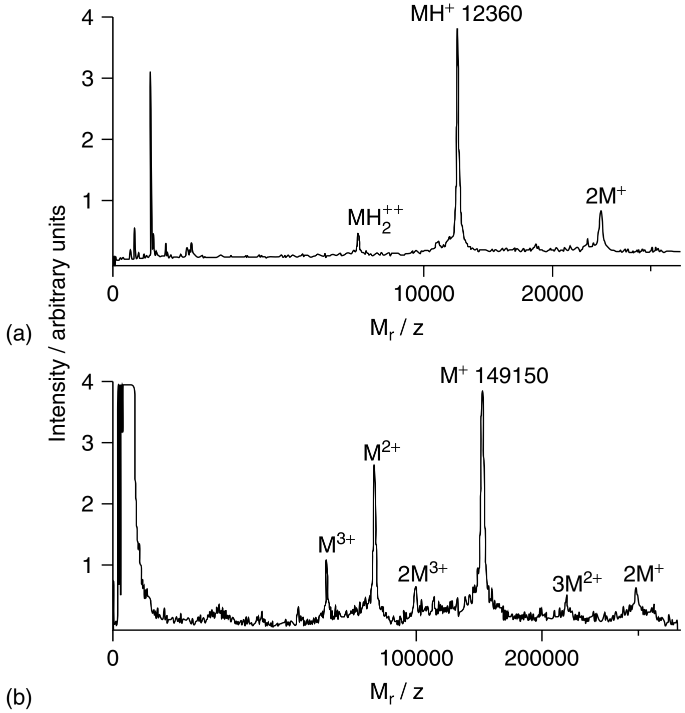

Fig. 29.28 Two UV-MALDI spectra of the early days of MALDI immediately demonstrating the potential of the method. (a) The small protein porcine cytochrome C from 2,5-dihydroxybenzoic acid matrix after accumulation of 20 laser shots and (b) a large monoclonal antibody from nicotinic acid matrix after accumulation of 30 laser shots. Although assigned as $M^{+\bullet}$ or $[M + H]^+$ ions, it may be assumed that the signals are formed by the whole palette of quasimolecular ions possible. Reproduced from Karas, Bahr and Gießmann (1991) with permission. © John Wiley & Sons Inc., 1992.

(Karas *et al.*, 1989a; Karas *et al.*, 1989b; Karas, Bahr and Gießmann, 1991) A majority of portions of the research done in these fields today rely on MALDI as a (high-throughput) method for fingerprinting (Welham *et al.*, 2000), identifing, and sequencing of various classes of biopolymers (Hillenkamp and Peter-Katalinic, 2007).

The tremendous development of TOF instruments was initiated and put forward to a large extent by the demand for increasingly powerful MALDI instrumentation. Indeed, MALDI-TOF was the almost indivisible implementation of MALDI in its first decade.

The instrumental setup for MALDI does not differ from LDI; the matrix is the key to the method's success. The matrix provides effective absorption of the laser energy independent of whether the analyte possesses a chromophore or not. It separates the molecules before evaporation and supports the ionization process, either by acid/base reactions upon mixing with the analyte or during the actual desorption via ion–molecule reactions in the laser-generated plasma (e.g., cf. Sections 29.4.1.4, 29.4.2.1, 29.4.2.2) (Zenobi and Knochenmuss, 1999; Karas and Krüger, 2003).

Nitrogen UV lasers ($\lambda = 337$ nm) are most frequently employed to supply power in excess of the threshold irradiance for ion production ($>10^6$ W cm^{-2}). Nonetheless, excimer lasers ($\lambda = 293$, 248, 308, and 351 nm), frequency-tripled ($\lambda = 355$ nm), and quadrupled Nd : Yag lasers ($\lambda = 266$ nm) are also in use. In IR-MALDI, used for a minority of applications where penetration depth is important, for example, to desorb samples from gels or thin layer chromatographic (TLC) plates, Er : Yag lasers ($\lambda = 2.94$ µm) and CO_2 lasers ($\lambda = 10.6$ µm) are common (Overberg *et al.*, 1990; Overberg, Karas and Hillenkamp, 1991).

Although many standard applications of MALDI do not present very special requirements, MALDI sample preparation can be an art in itself. For certain types of analytes such as oligonucleotides or high-mass (bio)polymers, great care needs to be excised to produce suitable crystal layers where analyte and matrix are preferentially cocrystallized from solution in molar ratios in the 1 : 1000–100.000 (10^5) range. The same applies when ultimate sensitivity is required. Under optimal conditions, the sample consumption is in the low femtomole range, and several attomoles have been demonstrated (Vorm, Roepstorff and Mann, 1994). Special hydrophobic targets with hydrophilic spots effecting the concentration of the preparation on a small diameter spot (200–600 µm) deliver substantially improved sensitivity (Nordhoff *et al.*, 2003).

By selecting a matrix to the analyte's requirements, MALDI can be applied to a large variety of analytes ranging from nonpolar polymers such as (low MW) polyethylene to highly polar polymers such as poly(toluenesulfonic acid) resins. It is suitable for peptides, proteins, oligonucleotides, and DNA, for oligosaccharides (Figure 29.29), and – sometimes overlooked – for small molecule analysis, for example, for dyes, lipids, and porphyrins.

MALDI-MS presents a powerful method for the analysis of proteins and peptides. It may be used for the in-depth analysis of an individual protein to reveal its primary structure, that is, its amino acid sequence, as well as eventual (posttranslational) modifications (Figure 29.30). Proteomics, the

study of the whole complexity of a protein mixture expressed by given type of cells, is another widespread application of MALDI, which indeed serves as a propellant for the steady improvements in sensitivity, resolution, mass accuracy, and speed of modern MALDI instrumentation. It is a common procedure to obtain survey MALDI spectra of protein tryptic digests and to subsequently measure MALDI tandem mass spectra of the tryptic peptides produced. The sequence of the whole protein may then be derived by putting the subsequences of those peptides together (Lehmann, 1996; Kinter and Sherman, 2000; Snyder, 2000).

In polymer chemistry, MALDI spectra provide identification of the monomer (repeat unit), of the average molecular weight, and of polydispersity, and – provided the low-mass end of the envelope is not beyond m/z 1000 – allow for end group analysis (Figure 29.31) (Nielen, 1999; Murgasova and Hercules, 2003; Montaudo and Lattimer, 2001; Pasch and Schrepp, 2003).

29.8
Ion Formation at Atmospheric Pressure

It is a common feature of the ionization methods discussed so far that the process of ion formation occurs under vacuum conditions, varying from the high vacuum in EI or FI to the low-pressure limit of medium vacuum in the case of CI. Although passing through a steep pressure gradient across the selvedge region, even the deliberation of ions in desorption/ionization methods proceeds from a surface located in vacuum. It is inherent to these methods that they cannot deal with a noteworthy liquid flow, a fact

preventing – or at least strongly limiting (cf. CF-FAB, Section 29.7.2) – their successful combination with LC. Nonetheless, there was a long-standing desire to develop *liquid-chromatography-mass spectrometry coupling* (LC-MS) in order to address highly polar analyte mixtures.

Atmospheric pressure ionization (API) methods take the very step of ion formation virtually to the outside of the mass spectrometer, or they expand the mass spectrometer into the laboratory atmosphere.

29.8.1
Atmospheric Pressure Ionization

The first implementation of a continuous liquid flow coupled to a mass analyzer was presented by Horning *et al.* as early as 1973 and was termed API (Horning *et al.*, 1973; Horning *et al.*, 1974). In API, the sample solution is evaporated at atmospheric pressure by a heated stream of nitrogen gas. The vapor is then passed along a ^{63}Ni foil, the electrons emitted from which start a series of ion–molecule reactions, leading to $[(H_2O)_n{+}H]^+$ cluster ions that finally cause $[M{+}H]^+$ ions to be formed. Although most of the gas is removed by a rotary pump, a portion is admitted to a quadrupole mass analyzer through a small orifice (Figure 29.32). Although API itself is not anymore in use, the method has coined the name for a whole family of ionization methods.

To improve ionization efficiency, the same group soon introduced *atmospheric*

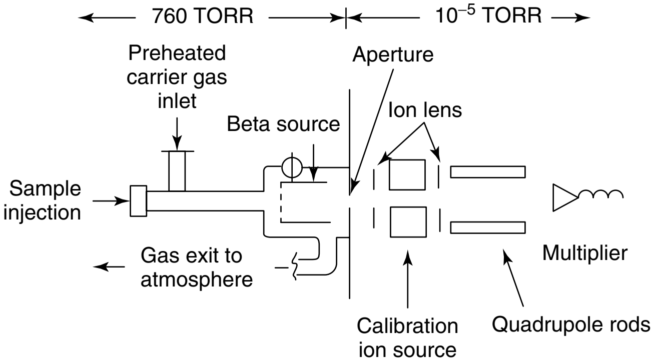

Fig. 29.32 Atmospheric pressure ionization (API) as introduced in 1973. The β-source initiates ion formation via a series of ion–molecule reactions involving water cluster ions. A small portion of the ions is transmitted into a quadrupole mass analyzer through an orifice. The quadrupole instrument shown in this first publication on API even had an EI ion source that could be used for calibration and testing of the instrument. Reproduced from Horning *et al.* (1973) with permission. © American Chemical Society, 1973.

pressure chemical ionization (APCI) where the formation of ions is achieved without the aid of radioactive ^{63}Ni. Here, electrons are delivered by a corona discharge from a needle tip pointing into the sample vapor or by admitting electrons produced from a heated filament as in CI (Carroll *et al.*, 1975; Dzidic *et al.*, 1976). The fact that the ion–molecule reactions take place at atmospheric pressure led to the term. Highly improved setups of APCI still present common LC-MS equipment (cf. Section 29.8.3) (Niessen and Voyksner, 1998; Niessen, 1998).

Another important approach to LC-MS was the *thermospray* (TSP) interface (Blakley, Carmody and Vestal, 1980; Blakley and Vestal, 1983). In TSP, the analyte solution flowing at 1–2 ml min^{-1} is rapidly vaporized by passing it through strong heater. Positive ions are formed by protonation or electrophilic addition of cations, negative ions by deprotonation or nucleophilic addition, for example, by 0.1 M ammonium acetate added to the solution before evaporation. The ions are extracted orthogonally from the vapor phase and enter the mass analyzer through an aperture in the ion exit plate. The ionization efficiency of TSP interfaces can also be increased by the addition of a source for electrons, that is, by changing its operation basically to APCI mode.

In addition to these methods, some others were rather short-lived. The *particle beam interface* (PBI) employed conventional EI or CI ion sources to effect ionization of micrometer-sized solid particles produced upon room-temperature evaporation of low-polarity solvents, followed by removal of the vapor by a jet separator (Willoughby and Browner, 1984; Brauers and von Bünau, 1990). The *moving-belt interface* transported the solid residues of solvent evaporation inside an oven into an EI or CI ion source where they were evaporated by heating the metal belt in analogy to the sample vial in standard EI or CI applications

(McFadden, Schwartz and Evans, 1976; Karger *et al.*, 1979; McFadden, 1979).

29.8.2
Electrospray Ionization

Electrolytic solutions can be dissipated to form a mist of highly charged micrometer-sized droplets by the action of a strong electric field. This process, known as *electrospray*, is based on Zeleny's work on the behavior of surfaces under the influence of electric fields (Zeleny, 1917) and Taylor's observation that spheric droplets then take the shape of a cone (*Taylor cone*) from which a fine liquid jet is emitted (Taylor, 1964) when Coulombic repulsion exceeds the surface tension, that is, when the *Rayleigh limit* is passed (Lord Rayleigh, 1882). Experiments by Dole demonstrated the production of gaseous ions from polymer solutions by electrospray (Dole *et al.*, 1968a; Dole *et al.*, 1968b), and finally Fenn's group developed an interface to a quadrupole mass analyzer. Their *electrospray ionization* (ESI) device was able to deliver multiply charged ions of large biomolecules, a discovery meaning the breakthrough for ESI (Whitehouse *et al.*, 1985; Fenn *et al.*, 1989; Fenn, 2003). Nowadays, both ESI and MALDI are essential tools of biomedical research (Figure 29.33) (Dole, 1997; Pramanik, Ganguly and Gross, 2002).

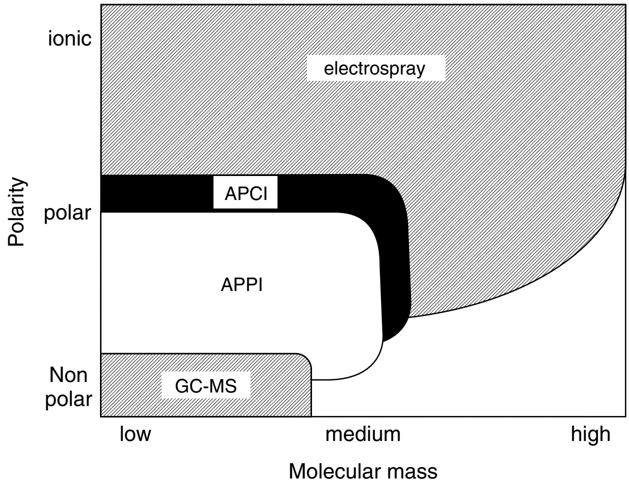

Fig. 29.33 The importance of ESI among chromatography-mass spectrometry applications can be inferred from its wide range of analyte acceptance in terms of both polarity and mass. ESI may deal with medium polar to ionic analytes ranging from as low as 10 u to as high as 10^6u in mass. APCI and APPI are very similar to each other in coverage, both accessing only the lower left segment of the polarity-mass plane in this illustration. Adapted with permission of U. Karst from cover of *Anal. Bioanal. Chem.* **378(4)** (2004).

When an electrolytic solution (typically 10^{-6}–10^{-4} M at 1–5 μl min^{-1}) reaches the end of a capillary (10–100 μm i.d.) that is connected to high voltage

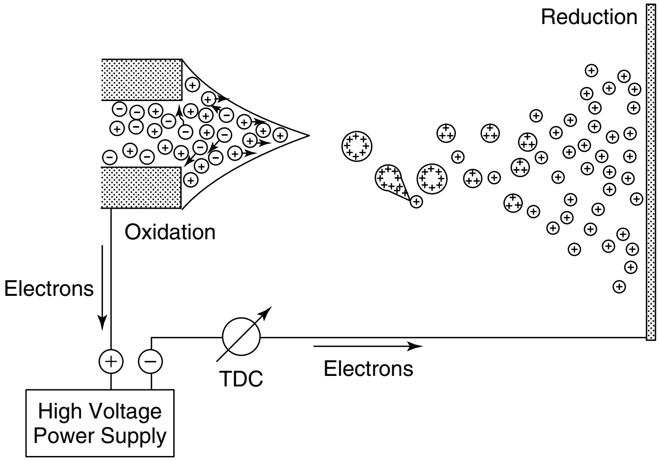

Fig. 29.34 The electrospray process is induced by charge separation at the tip of the spray capillary forcing the emerging droplet to form a cone. The increased electric field strength at cone's apex causes emission of a fine jet that breaks up to form micrometer-sized highly charged droplets that shrink upon evaporation of solvent. The overall process presents an electrolytic cell. To adapt ESI to a mass spectrometer, the counter electrode has a small hole that admits a portion of the aerosol. The sample flow may be supplied by either a liquid chromatograph or a syringe pump. Adapted from Kebarle and Tang (1993) with permission.

(3–5 kV), the electrospray process is induced. First, charge separation at the tip of the spray capillary forces the emerging droplet to form a cone. The increased electric field strength at the apex of the cone then causes emission of a fine jet that soon breaks up to yield micrometer-sized highly charged droplets shrinking upon evaporation of solvent. The overall process represents an electrolytic cell (Figure 29.34) (Kebarle and Tang, 1993). ESI can be adapted to a mass spectrometer when the counter electrode has a small hole to admit a portion of the aerosol via a differentially pumped interface. The principle of a differentially pumped interface has already been outlined (Section 29.5.4, Figure 29.10). However, opposed to the plasma conditions in ICP, the ESI sprayer is operated at room temperature, in fact, in the laboratory atmosphere. To compensate for the heat of evaporation, that is, to prevent droplets from freezing during desolvation while traveling through the interface, some external heating is required. Heating may be realized in either way, using a slow counter current of hot nitrogen gas (1–2 l min^{-1} at 150–250 °C), or transfer of the aerosol through a heated capillary (ca. 0.5 mm i.d., 10 cm length, 120–220 °C), before the first pumping stage.

The shrinking of the droplets causes ejection of much smaller droplets when the critical charge density is reached. Those off-spring droplets carry only a minor portion of the mass, but a significant portion of the charges of their precursor. After repeated *droplet jet*

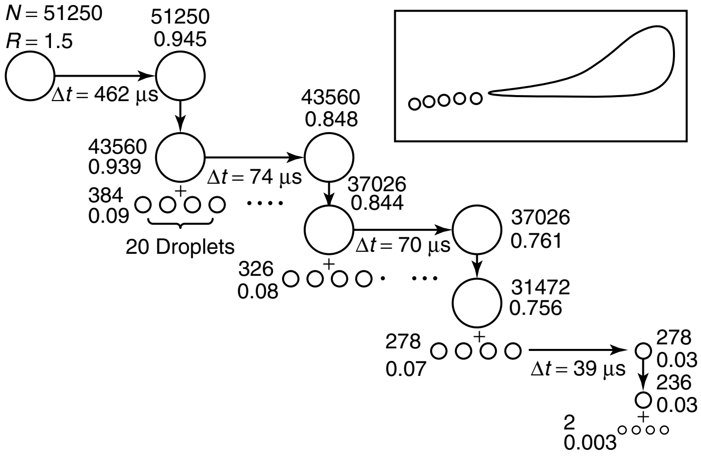

Fig. 29.35 Illustration of droplet jet fission that leads to a stepwise reduction in droplet size. The inset shows the fission process whereby a series of smaller, nonetheless highly charged, off-spring droplets is released from a precursor droplet. Adapted from Kebarle and Tang (1993) with permission.

fission, it comes to the step of production of isolated gas phase ions (Figure 29.35) (Kebarle and Tang, 1993; Cole, 2000; Kebarle, 2000). The ultimate step of ESI, the deliberation of unsolvated gas phase ions, may proceed on one of the following ways: (i) macromolecules can undergo multiple protonation or cationization in solution up to a level where Coulombic repulsion between the charges poses a limit. Those ions may then remain while all solvent molecules evaporate (*charged residue model*). (ii) For small ions, *ion evaporation* may be taken into account, that is, the shrinking droplet may reduce the charge density by emission of ions from its surface.

In recent interface designs, the sprayer is not in line of sight with the analyzer, but roughly at right angle to the entrance (orthogonal sprayer), and eventually the skimmer may be at right angle to the beam direction of the first pumping stage (z-spray). All these adjustments aim at improving the ion transmission, while reducing the load of neutrals (residual gas, solvent vapor) and unwanted ions (buffer salts) onto the system, thereby optimizing the robustness of the interface (Fenn *et al.*, 1990; Ikonomou and Kebarle, 1994; Abian, 1999). To adapt ESI to higher flow rates (10–1000 μl min^{-1}), most modern ESI sprayers offer pneumatic assistance, that is, a nebulizer gas flow emerging from a fine gap around the spray capillary.

On the other hand, to reduce sample flow and thus the extent of use of precious samples, nano-ESI may be employed. In nano-ESI, the analyte solution is supplied in a (single use) glass capillary, drawn to form a fine tip where a small aperture (1–5 μm) allows the generation of a particularly fine spray. High voltage is connected via the metal-coated outside of the capillary. By adjusting the nano-ESI sprayer very close to the entrance of the interface, the ratio of

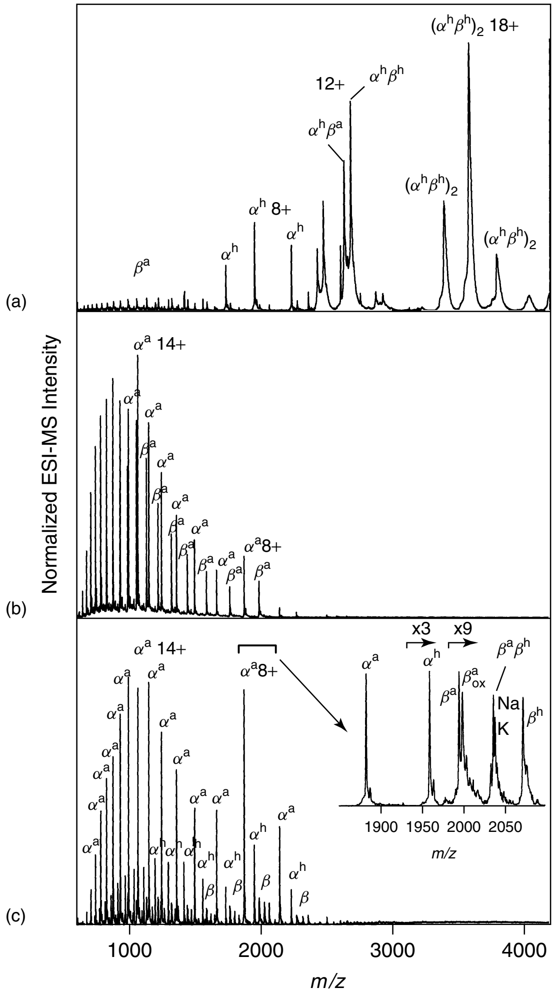

Fig. 29.36 ESI mass spectra of hemoglobin recorded under different solvent conditions. admitted to rejected aerosol is significantly improved (Wilm and Mann, 1994; Wilm *et al.*, 1996; Wilm and Mann, 1996). Thus, 1 µl of sample can deliver a 20-min lasting spray at 50 nl min^{-1} while the ion current of the mass spectrometer does not remarkably drop as compared to conventional ESI operation. Beside lower sample consumption, nano-ESI offers operation free of memory from previous samples and access to low volatility solvent systems such as 100 % water or water/dimethylsulfoxide mixtures. On the other side, the metal plated, sometimes precision-cut, capillaries are expensive and fragile and require an experienced operator.

The application of ESI to biopolymers such as proteins, oligosaccharides, or DNA delivers a distribution of charge states, either positive or negative as required by the analyte. Normally, the charge state distribution represented by all peaks belonging to one analyte species forms an even envelope. In the case of proteins for example, it has a maximum at one charge per 1000 u. This way, ESI "folds" high-mass analytes into the *m*/*z* range of most mass spectrometers (Peng and Gygi, 2001; Hanson *et al.*, 2003). The charge state distribution of a protein is not independent of the experimental conditions; on the contrary, it is subject to remarkable changes upon pH and, thus, protein tertiary structure. However, ESI not only provides molecular mass but also allows information on the shape of macromolecules to be derived (Figure 29.36) (Boys and Konermann, 2007). Combined with the extraordinary softness of ion generation, ESI can indeed supply "wings to molecular elephants" (Fenn, 2003).

1. It is possible to calculate charge states for all peaks of the distribution from which, in turn, the mass of the neutral analyte can be deduced (Covey *et al.*, 1988; Mann, Meng and Fenn, 1989).
2. This is due to the fact that the charge state of the ions forming the signal at the adjacent lower *m*/*z* is higher by exactly one.
3. Today, software is available to do automated *charge deconvolution*.

ESI is soft enough to yield isolated gas phase ions of rather labile molecular assemblies such as host–guest complexes, adducts, or solvated species. Therefore, ESI is a well-established analytical tool in supramolecular chemistry (Chapter 5 in Schalley, 2007). In combination with tandem MS, ESI can also deliver information on the stability of such complexes (Figure 29.37).

Advantageous on one side, the inherent softness of ESI yields mass spectra highly reliable for molecular mass and molecular formula determination, but often without fragment ions that could serve for structure elucidation. Therefore, ESI is frequently combined with tandem mass spectrometric methods to compensate for that lack (activation methods cf. Section 29.9). Among these, *collision-induced dissociation* (CID) is the most standardized and widespread technique, for example, CID is the standard tool for peptide sequencing (Figure 29.38) (McLafferty, 2001).

Finally, ESI is well applicable to (ionic) metal complexes. This way, ESI nicely complements the capabilities of FAB and FD, in particular LIFDI. Especially, syringe pump infusion delivers a signal highly constant in time, which provides the basis for advanced experiments, for example, catalyst screening by ion–molecule reactions (Figure 29.39) (Volland *et al.*, 2001; Chen, 2003; Adlhart and Chen, 2003).

29.8.3
Atmospheric Pressure Chemical Ionization and Atmospheric Pressure Photoionization

Modern ion sources for APCI (Keski-Hynnilä *et al.*, 2002) and *atmospheric pressure photoionization* (APPI) (Robb, Covey and Bruins, 2000; Kauppila *et al.*, 2002; Raffaeli and Saba, 2003) are based on ESI interfaces. For APCI, the complete interface from atmospheric pressure to analyzer entrance remains unaltered, whereas the ESI sprayer is exchanged for the heated vaporizer and a corona needle is placed in the space between vaporizer exit and interface entrance. For APPI, the same vaporizer may be used, but the corona needle is replaced by a rare gas discharge UV lamp; for example, a krypton lamp delivers 10-eV photons (Figure 29.40)

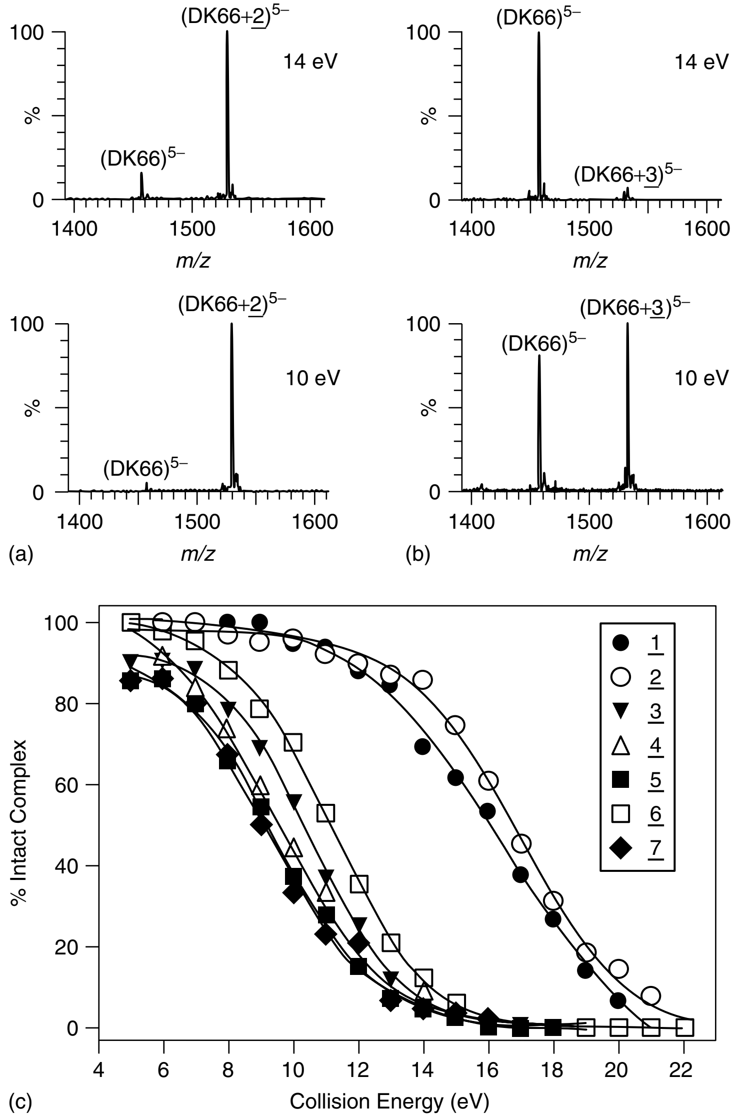

Fig. 29.37 Negative-ion ESI tandem MS experiments on $[1{:}1]^{5-}$ complexes with the d(CGCGAATTCGCG)$_2$ duplex (DK66). Representative tandem mass spectra obtained with different ligands: (a) benzopyridoindole drug (**2**) and (b) benzopyridoquinoxaline drug (**3**), using collision energies of 10 and 14 eV. The increased dissociation upon more energetic collisions is obvious. The argon pressure inside the RF-only hexapole collision cell was 3×10^{-5} mbar. (c) Derived breakdown graphs of different intercalator drugs with DK66 allow to derive the relative binding strengths of those drugs to the duplex; stronger binding causes the curves to shift to the right. (Keski-Hynnilä *et al.*, 2002; Raffaeli and Saba, 2003).

The types of ions are formed depend on the solvent and the analyte. In positive-ion mode, $[M + H]^+$ ions and products of electrophilic addition are preferred with polar combinations, whereas CT will occur to yield $M^{+\bullet}$ ion for unpolar systems (cf. PICI). Although PI of the analyte also plays a role in APPI, it is less

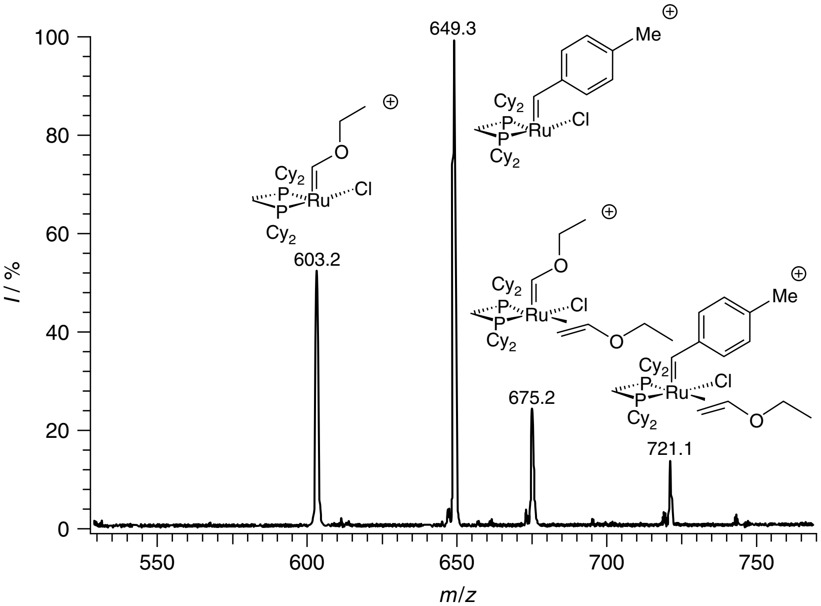

Fig. 29.39 ESI tandem MS experiment for catalyst screening via ion–molecule reactions. The mass-selected precursor ion, [(dcpm-κ^2P)ClRu=CH(p-C_6H_4Me)]$^+$, m/z 649, is reacted with ethyl vinyl ether upon collision in the RF-only octopole collision cell of a triplequadrupole instrument at a collision energy of 1 eV. The product ions incorporating the ether molecule are observed at m/z 603, 675, and 721. Reproduced from Volland *et al.* (2001) with permission. © Wiley-VCH, 2001.

pronounced than one would expect. Unfortunately, there is a tendency in APPI to form radical ions and closed-shell at the same time so that isotopic patterns suffer from superimposition of both species. Analogously to positive-ion mode, operation in negative-ion mode resembles conventional NICI. However, the AP versions of PICI and NICI are slightly softer than their vacuum counterparts, because vaporization from solution reduces "thermal stress" of the analyte and the large number of low-energy collisions at atmospheric pressure serves to keep the ions thermalized.

Both APCI and APPI serve for similar types of analyses. Mostly they are employed as ionization methods in LC-MS applications for low-to-medium polarity analytes, that is, when active ionization of neutrals is required because ion formation in solution is ineffective (Abian, 1999; Tsuchiya, 1995; Reemtsma, 2003). Illustrative examples are the characterization of natural polyamines in spider venom (Figure 29.41) (Chesnov, Bigler and Hesse, 2002), metabolites of pharmaceuticals in human plasma (Yang and Henion, 2002) and PAHs (Hayen and Karst, 2003).

The desire to have MALDI attached to other analyzers made it necessary to reduce the large energy spread (tens of electron volts) of the laser desorbed ions. This can be accomplished by thermalization with gas, either by having a pulsed valve admitting nitrogen or argon before each laser shot or by moving the event of desorption/ionization into a region of medium vacuum. It turned out that MALDI can even be realized at atmospheric pressure (Laiko, Baldwin and Burlingame, 2000a; Laiko, Moyer and Cotter, 2000b; O'Connor and Costello, 2001; Doroshenko *et al.*, 2002). By positioning a MALDI target in front of the interface, the freshly generated and thermalized ions are guided directly into the instrument (Figure 29.42). Different from APCI and APPI, switching the mode of operation to AP-MALDI is slightly more demanding due to the requirement for accurate alignment of target and laser optics. In addition, sensitivity of AP-MALDI is generally lower than that of vacuum MALDI. The true advantage of atmospheric pressure MALDI (AP-MALDI) is its compatibility with AP

sources, which offers more flexibility for the use of expensive equipment.

29.8.5
Desorption Electrospray

For ESI, the analyte is normally supplied in dilute electrolytic solution. Nonetheless, Takats *et al.* discovered that the processes of electrospraying and sampling can be separated in a way that the electrostatically charged aerosol is blown onto a surface from which analyte molecules are sampled and ionized (Takats *et al.*, 2004; Chen *et al.*, 2005). This method was termed *desorption electrospray/ionization* (DESI). DESI transforms the step of sample preparation into a mere positioning of sample between the sprayer and entrance. DESI obviously plays to its strengths for the quick analysis of surface (adsorbed) compounds such as alkaloids in plants (Figure 29.43), pesticides on fruit, explosives on cloths and similar items, control of bulk compounds, and other applications where the target compound class is defined (Popov *et al.*, 2005; Takats *et al.*, 2005a; Takats, Wiseman and Cooks, 2005; Talaty, Takats and Cooks, 2005).

29.8.6
Direct Analysis in Real Time

Another recent addition to the repertoire for rapid, noncontact analysis at ambient pressure is presented by *direct analysis in real time* (DART) (Cody, Laramee and Durst, 2005) DART differs much from the aforementioned techniques. It is based on the reactions of electronic or vibronic excited-state species with

reagent molecules, that is, basically on Penning ionization. A stream of nitrogen or helium gas is passed through an high-voltage electrical discharge to generate the excited molecules or atoms that then exit as a directed stream at 1 l min^{-1}. The analyte is exposed to this ionizing gas stream in proximity to the entrance of an API interface.

DART can be applied to the analysis of gases, liquids, and solids on various surfaces. As such, DART provides a very sensitive tool for the detection of explosives, the characterization of inks on paper, and the analysis of residual components from hygiene products (Figure 29.44) (Jones, Cody and McClelland, 2006; Yew, Cody and Kravitz, 2008; Haefliger and Jeckelmann, 2007; Williams *et al.*, 2006).

29.9
Activation Methods for Tandem Mass Spectrometry

The term *tandem mass spectrometry* refers to all techniques where ions mass selected by a first stage are subjected to some type of activation (or less frequently chemical reaction) before the product(s) of this process are mass-analyzed on a second stage of the instrument (McLafferty, 1983; Busch, Glish and McLuckey, 1988). On beam instruments,

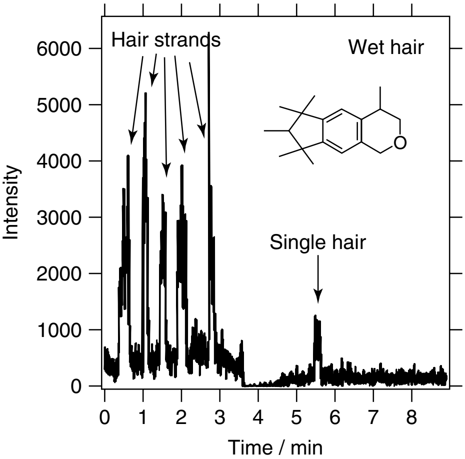

Fig. 29.44 DART-SRM analysis of hair washed with shampoo that contained 0.5% galaxolide® fragrance (musk replacement). The target compound was even identified from a single hair. SRM stands for *single reaction monitoring*, a mode of tandem MS operation where a selected fragment ion, here *m*/*z* 227, is detected only if produced from a given precursor; in this case $[M + H - H_2]^+$, *m*/*z* 257; SRM significantly improves the selectivity of an analysis. Adapted from Haefliger and Jeckelmann (2007) with permission. © John Wiley & Sons Ltd, 2007.

tandem MS requires a second mass analyzer behind the zone of activation; hence, this is sometimes referred to as *tandem in space*. On ion traps of any type, the sequence of selection, activation, and product analysis is usually effected inside the same unit by applying different modes of operation. Owing to its sequential character, this is then termed *tandem in time*. The activation step can be performed in many ways; the most common techniques are listed in Table 29.4. Table 29.5 lists the most important symbols in MS.

Tab. 29.4 Common activation methods for gas phase ions.

Method	**Acronym**	**Basic principle of ion excitation**	**Instrumentation**
Collision-induced dissociation (outdated terms: collisional activation, collisionally activated dissociation)	CID (outdated acronyms: CA, CAD)	Kinetic energy of ions is converted into vibrational excitation upon collisions; high-energy CID refers to keV ions typically once collided with He; low-energy CID refers to ions of 1–100 eV typically multiply collided with Ar (McLafferty, 1983; Busch, Glish and McLuckey, 1988). Suitable neutrals provided, collisions at very low energy can lead to chemical reactions (cf. Figure 39)	Suitable (scan) techniques for all types of mass analyzers available; independent of ion polarity
Infrared multiphoton dissociation	IRMPD	Absorption of IR photons provides vibrational excitation (Woodin, Bomse and Beauchamp, 1978; Watson, Baykut and Eyler, 1987)	On FT-ICR instruments; independent of ion polarity
Electron capture dissociation	ECD	Multiply charged positive ions undergo bond cleavage upon partial neutralization by capturing a thermal electron (Zubarev, Kelleher and McLafferty, 1998; Axelsson *et al.*, 1999)	On FT-ICR instruments; for multiply charged positive ions only
Electron transfer dissociation	ETD	Same effect as ECD, but negative radical ions are supplied (reagent ions) as the source of electrons (Coon *et al.*, 2005; Syka *et al.*, 2004)	Linear and three-dimensional quadrupole ion trap, orbitrap; for multiply charged positive ions only

Tab. 29.5 The most important symbols in mass spectrometry.

Symbol	Term	Explanation
$M^{+\bullet}$ ($M^{-\bullet}$)	Molecular ion	Positive (negative) ion formed from a molecule by removal (addition) of an electron
$[M + H]^+$, $[M + Na]^+$, $[M + NH_4]^+$, and so on	Quasimolecular ion	Ions formed instead of the molecular ion, but very closely related to it. The term also applies to $[M + Na]^+$, $[M + K]^+$ or $[M + Cl]^-$ ions, for example
MS	Mass spectrometry	Refers to the method; do not use it for a spectrum or instrument
MS/MS or MS^2	Tandem mass spectrometry	Mass-selected ions are subjected to fragmentation or reactions, the products are analyzed on a second stage
MS^3, MS^n	Tandem mass spectrometry	Higher order tandem MS experiments
m/z	Mass-to-charge ratio	Dimensionless ratio of the mass number and the number of elementary charges of an ion. The position of peaks on the abscissa of a mass spectrum is stated as "at m/z x"
u	Unified atomic mass	SI unit for atomic mass defined as 1/12 of the mass of the nuclide ^{12}C; $1\ u = 1.66055 \times 10^{-27}$ kg
B	Magnetic sector	Of a sector instrument
E	Electrostatic sector	Also termed ESA, electrostatic analyzer
ICR	Ion cyclotron resonance	To denote the method as well as the ICR cell of an instrument
LIT	Linear quadrupole ion trap	
Q and q	Quadrupole	Q for mass separating, q for RF-only ion guides
QIT	Quadrupole ion trap	A "three-dimensional" trap
TOF	Time of flight	To denote the method as well as theTOF analyzer of an instrument

Acronyms

AMS	Accelerator mass spectrometry
AE	Appearance energy
APCI	Atmospheric pressure chemical ionization
API	Atmospheric pressure ionization
AP-MALDI	Atmospheric pressure matrix-assisted laser desorption/ionization
APPI	Atmospheric pressure photoionization
CE	Capillary electrophoresis
CE	Charge exchange (equivalent to CT)
CF	Continuous flow
CF-FAB	Continuous-flow fast atom bombardment
CI	Chemical ionization
CID	Collision-induced dissociation
CT	Charge transfer
DART	Direct analysis in real time
DESI	Desorption electrospray/ionization
DIOS	Desorption/ionization on porous silicon
EA	Electron affinity
EC	Electron capture
ECD	Electron capture dissociation
EHC	Emitter heating current
EI	Electron ionization
ESI	Electrospray ionization
ETD	Electron transfer dissociation
FAB	Fast atom bombardment
FD	Field desorption
FI	Field ionization
FT-ICR	Fourier-transform ion cyclotron resonance
GC-MS	Gas chromatography-mass spectrometry
GD	Glow discharge
ICP	Inductively coupled plasma
IE	Ionization energy
IR-MS	Isotope ratio mass spectrometry
IR-MALDI	Infrared matrix-assisted laser desorption/ionization
IRMPD	Infrared multiphoton dissociation
LA	Laser ablation
LC-MS	Liquid-chromatography-mass spectrometry
LDI	Laser desorption/ionization
LIFDI	Liquid injection field desorption/ionization
LSIMS	Liquid secondary-ion mass spectrometry
MALDI	Matrix-assisted laser desorption/ionization
M_r:	Relative molecular mass (equal to MW)
MS	Mass spectrometry (not to be used for mass spectrometer or mass spectrum)
MS/MS	Mass spectrometry/mass spectrometry or tandem mass spectrometry
MUPI	Multiphoton ionization
MW	Molecular weight
Nano-ESI	Nanoelectrospray ionization
NCI	Negative-ion chemical ionization
NICI	Negative-ion chemical ionization
PA	Proton affinity
PCI	Positive-ion chemical ionization
PICI	Positive-ion chemical ionization
ppb	Parts per billion
ppm	Parts per million
QET	Quasi-equilibrium theory

RE	Recombination energy
REMPI	Resonance-enhanced multiphoton ionization
RF	Radio frequency
SIM	Selected ion monitoring
SIMS	Secondary-ion mass spectrometry
SRM	Selected reaction monitoring
SS-MS	Spark source mass spectrometry
TI	Thermal ionization
TOF	Time of flight
TSP	Thermospray
UV-MALDI	Ultraviolet matrix-assisted laser desorption/ ionization

31.1
Introduction

31.1.1
Origins

The word *chemometrics* is said to have been coined in the early 1970s by the Swedish organic chemist Svante Wold in submitting a grant application. Over that period there were many groups working in what might in modern parlance be referred to as *chemometrics*, but which was, at the time, called by other names such as *chemical pattern recognition, machine learning*, or *laboratory optimization*. These diverse groups often published the subject in different journals: emerged as a discipline seriously in 1980s, with the organization of a School in Cosenza, Italy, in 1983 (Kowalski, 1984), the founding of two journals in 1986 (Chemometr. Intell. Lab Syst.) and 1987 (J. Chemometrics), and the publication of the first text books (Sharaf, Illman and Kowalski, 1986; Massart *et al.*, 1988; Martens and Næs, 1989; Massart and Kaufmann, 1983; Malinowski and Howery, 1980). These books have been widely used; for example, by January 2008 Martens and Næs (1989) had been cited 3145 times, Malinowski and Howery (1980) including two subsequent editions 2164 times, and Massart *et al.* (1988) 1432 times. As an example of the rapid growth of interest over the past two decades, citations per year for Martens and Næs (1989) are shown in Figure 31.1; now there are two sequels from these authors that are cited more often (Naes *et al.*, 2002; Martens and Martens, 2000). In the next two decades, there were many very significant books written on the subject (Brereton, 2003; Massart *et al.*, 1997; Vandeginste *et al.*, 1998; Otto, 1998; Beebe, Pell and Seasholtz, 1998; Kramer, 1998; Gemperline, 2006; Brereton, 2007; Massart *et al.*, 1990; Brereton *et al.*, 1992; Adams, 2004; Meloun, Militky and Forina, 1992; Meloun *et al.*, 1994; Brereton, 1992; Mark and Workman, 2003; Haswell, 1992; Esbensen, 2002; Eriksson *et al.*, 2001) often from different viewpoints.

The earliest practitioners of the subject were not primarily regarded as chemometrics experts, but worked in areas such as pharmacy, analytical chemistry, process chemistry, and organic chemistry. New subjects are often slow to develop in academia, as they often have to work within the boundaries of quite well established disciplines to fit within historic departmental structures, and a

research base needs to be established according to funding patterns that dictate applications.

31.1.2
Development

Historically, however, there was a major development in near infrared (NIR) spectroscopy in the 1980s as cheap, cost-effective probe technology emerged, and there were several important areas of application including process monitoring especially in petrochemical and later in pharmaceutical industries and food chemistry that catalyzed early chemometrics applications. NIR data often involve several highly overlapping peaks that cannot be easily separated or deconvoluted to build a picture of the composition of a mixture. However, NIR is ideal for looking at the overall properties of mixtures and many industrial products, such as food or petrol, that consist of a mixture of compounds. Hence, a method of spectroscopy that is cost effective and can rapidly (and often noninvasively without the need to sample) measure properties that depend on the mixture as a whole has significant advantages. NIR instruments are often stable and have low noise levels. This, however, means that statistically based approaches are required to relate the NIR spectra to the characteristics of a product or process such as acceptability and origins, and this provided a major early driving force for chemometrics. Almost all NIR instruments have a chemometrics capability and this classical area of application is well established with well-described algorithms and a high standard of software. Other spectroscopies have followed suit, especially in cases where technology has improved; for example, cost-effective probes for ultraviolet/visible (UV/vis) spectroscopy have been developed over the past decade, and with most pharmaceuticals having prominent chromophores, the application of chemometrics in reaction monitoring and product quality assessment using UV/vis and chemometrics has grown significantly.

At the other end of the scale, there is a large amount of exploratory work that can be performed using larger instruments such as acoustic spectroscopy, NMR (Nuclear Magnetic Resonance), and MS (Mass Spectrometry), which also provide rich pickings for the chemometrics expert.

31.1.3
Software and Methodology

Often there is a confusion between software capability and chemometrics methodology. In many cases, there are a large number of methods available for the analysis of spectroscopic data but only a small fraction are incorporated into user-friendly software. This is because of the economics of developing software packages, often with a quite specialist market. A package that is tailored for a less common application, such as acoustic spectroscopy, may take as long to develop and cost as much in resources as one for a widespread area such as NIR. Hence, people who are not good programmers are often restricted to prepackaged methods that are primarily targeted toward quite a restricted set of applications. Although basic methods such as principal components analysis (PCA) are widely available, most spectroscopies pose quite specific data analytical problems and require quite specific strategies before pattern recognition. Another problem is that the originators of many of the chemometric-based software companies, most of which were founded in the 1980s, were primarily focused on common methods such as PCA and partial least squares (PLS), and also developed approaches, such as cross validation, that were very efficient in usage of computer power. Moore's law states that computing power doubles approximately every 18 months: on that basis, in a period of 20 years, computing power has increased by a factor of 2^{13} or about 10 000. This means that a calculation that could be performed in a week on a desktop PC in the mid-1980s required only 1 minute 20 years later. Hence, new and much more computationally intense, methods can be conceived and implemented and can provide an assessment of a spectrum within a very short time span compared to those used two decades ago, when chemometrics methodologies started to become commercially viable. The problem here though is that software developers need to keep pace – and the human investment in programming has not changed significantly – programmers are not 10 000 times faster at producing code : with new development tools perhaps code can be developed 2 or 3 times faster than 20 years ago but not more. Therefore, a large amount of the commercial packaged software that is available is based on the philosophy of the mid-1980s, and many spectroscopists who do not have the time or expertise to develop their own code are trapped within this environment, even though if one were to start from the beginning again perhaps quite different methods would become widespread. Areas such as bioinformatics have a more recent vintage and users often do not require real-time desktop solutions. They are happy to perform data mining on a remote mainframe and most users are programmers in their own rights. Hence new methods based on machine learning can easily be incorporated. However, this problem means that there is a gap opening up between the application-based laboratory user of packaged chemometrics software who is often quite limited in the methodology that can be applied and the pioneering research groups that can implement code rapidly but do not have the resources (or investment) to develop user-friendly benchtop software.

31.1.4
Multivariate Matrices

Most of chemometrics is characterized by signals that are multivariate, that is, they are best described in two dimensions and are commonly represented by matrices as in Figure 31.2. Chemometric methods are most valuable when there are several spectra, which are normally represented as rows (often called *samples*) of the multivariate matrix. The columns of the matrix represent the sensors, normally wavelengths (or frequencies). The elements of the matrix are the raw spectroscopic measurements, usually the intensity of a spectrum at a specific wavelength.

We do not discuss experimental design or signal preprocessing (e.g., derivatives and smoothing) in this chapter but these are normally important parts of the data analytical procedure.

31.1.5
Notation

At this point, we digress to give a short introduction to matrices. Matrix notation is generally useful throughout chemometrics.

In this chapter, we employ recommended notation as follows.

- A scalar (or a single number, e.g., a single concentration) is denoted in italics, for example, x.
- A vector (or a row/column of numbers, e.g., a single spectrum) is denoted by lower case bold roman, for example, $\mathbf{x}$.
- A matrix (or a two-dimensional array of numbers, e.g., a set of spectra) is denoted by upper case bold roman, for example, $\mathbf{X}$. Scalars and vectors can also be regarded as matrices, one of whose dimensions is equal to 1.

The dimensions of a matrix are characterized by the number of rows (e.g., the number of spectra) and the number of columns (e.g., the number of wavelengths). Hence, a dataset that consists of 20 spectra recorded at 1000 wavelengths can be arranged as a 20 × 1000 matrix, with 20 rows and 1000 columns.

The inverse of a matrix is denoted by "-1" so that $\mathbf{X}^{-1}$ is the inverse of $\mathbf{X}$. Only square matrices (where the number of rows and columns are equal) can have inverses. A few square matrices do not have inverses and this happens when the columns are correlated. The product of a matrix and its inverse is the identity matrix.

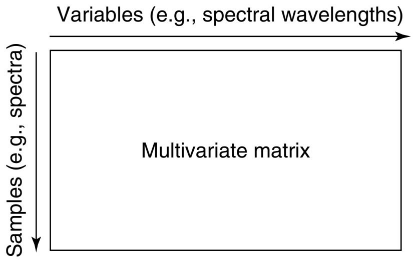

Fig. 31.2 Multivariate matrix as obtained in spectroscopy.

The transpose of a matrix is often denoted by "′" and involves swapping the rows and columns; hence, for example, the transpose of a 5 × 8 matrix is an 8 × 5 matrix.

Most people in chemometrics use the dot ("·") product of matrices (and vectors). For the dot product $\mathbf{X} \cdot \mathbf{Y}$ to be viable, the number of columns in $\mathbf{X}$ must equal the number of rows in $\mathbf{Y}$ and the dimensions of the product equal the number of rows in the first matrix and number of columns in the second one. Note that in general $\mathbf{Y} \cdot \mathbf{X}$ (if allowed) is usually different to $\mathbf{X} \cdot \mathbf{Y}$. For simplicity, sometimes the dot symbol is omitted, although it is always the dot product that is computed.

Finally, we introduce the concept a pseudoinverse of a vector or matrix, which is denoted as $\mathbf{X}^{+}$ so that if

$$\mathbf{Z} = \mathbf{X} \cdot \mathbf{Y} \tag{31.1}$$

$$\mathbf{Y} = \mathbf{X}^{+} \cdot \mathbf{X} \cdot \mathbf{Y} = \mathbf{X}^{+} \cdot \mathbf{Z} \tag{31.2}$$

It is important to note that only square matrices (where the number of columns and rows are equal) have mathematical inverses, but for matrices or vectors whose dimensions are not the same, there are two types of pseudoinverse, both of which can be denoted by $\mathbf{X}^{+}$, the right being

$$\mathbf{X}' \cdot (\mathbf{X} \cdot \mathbf{X}')^{-1}$$

and the left being

$$(\mathbf{X}' \cdot \mathbf{X})^{-1} \cdot \mathbf{X}'$$

The prime (′) implies a transpose, in which rows and columns are interchanged; for example, the transpose of a 5 × 8 matrix is an 8 × 5 matrix. When using vectors, the pseudoinverse mentioned above simplifies still further, but this is not discussed here.

31.2
Multivariate Curve Resolution

31.2.1
Motivation

An early and important application of chemometrics to spectroscopy involves signal resolution; this usually involves the determination of the number, characteristics, and relative amounts of compounds in a series of mixture spectra. Some authors call this *factor analysis*, some *multivariate curve resolution*, and others *deconvolution*. There is a vast array of techniques available to do this; however, only a few are summarized in this chapter. A historic text is by Malinowski and Howery (Malinowski and Howery, 1980) who developed a large array of approaches. This has been updated in a more recent edition (Malinowski, 2002). Multivariate signals often occur in, for example, reactions and involve recording a series of spectra as a function of time as different compounds change in relative concentration and in equilibria studies where each spectrum (e.g., taken at different pHs) is composed of several different spectroscopically active species. The objective is to obtain rate constants or to obtain equilibrium constants, as illustrated in Figure 31.3. The methods described in this section involve the determination of the (relative) concentrations of compounds in mixtures without the addition of external standards.

The initial step is to prepare the data, for example, by smoothing, baseline correction/derivatives, alignment if necessary, and a number of other approaches

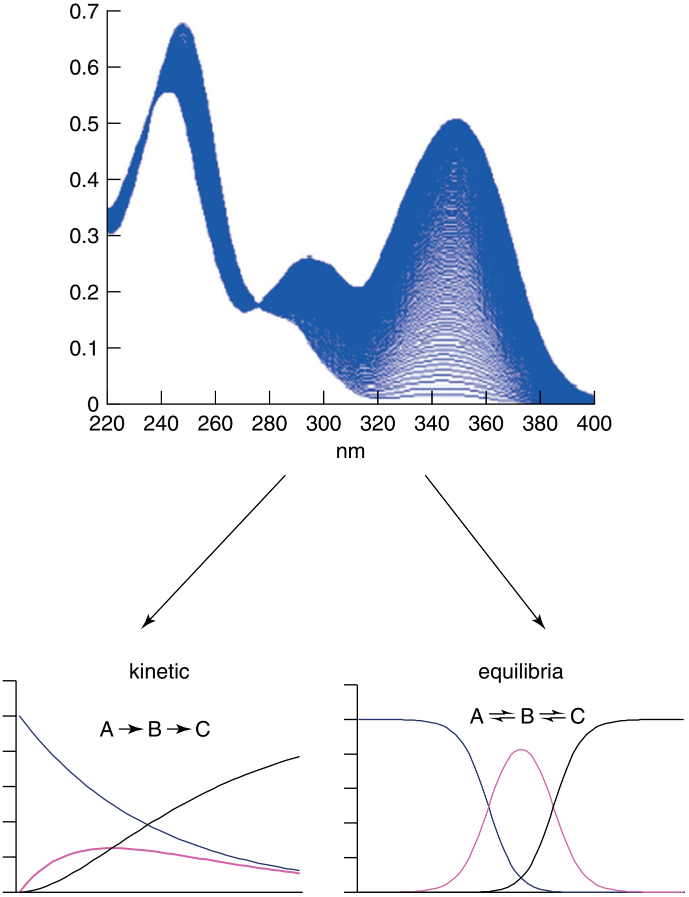

Fig. 31.3 Common motivations for resolving a series of spectra.

to reduce noise. However, these are not discussed in this chapter.

31.2.2
Principal Components Analysis

The first step is normally to perform PCA (Wold, Esbensen and Geladi, 1987; Joliffe, 1987). This common technique aims at converting an experimental data matrix from a series of spectra, which is arranged as a matrix **X** whose rows correspond to spectra (often taken at a specified time in a reaction pathway or pH in an equilibrium study) and whose columns correspond to spectroscopic wavelengths to a number of principal components (PCs) defined as follows:

$$\mathbf{X} = \mathbf{T} \cdot \mathbf{P} + \mathbf{E} \tag{31.3}$$

where

- **T** are called the *scores* and have as many rows as the original data matrix;
- **P** are the *loadings* and have as many columns as the original data matrix;

- the number of columns in the matrix **T** is equal to the number of rows in the matrix **P**; and
- **E** is an error matrix.

PCs are abstract mathematical entities with certain specific mathematical properties, the most important being the one that scores and loadings are orthogonal, that is, the vector product of any two different scores or loadings vectors is 0. There are several different algorithms for PCA including singular value decomposition (SVD) and nonlinear iterative partial least squares (NIPALS). Using NIPALS (which is being adopted in this chapter), the loadings matrices are also normal, that is, the sum of squares of their elements is equal to 1. Each column of **T** and row of **P** is a characteristic of a PC. The size of each successive PC is often called an *eigenvalue* and reduces for subsequent components. Eigenvalues can be defined mathematically as the sum of squares of each successive scores vector or column of **T**, but this definition depends on the algorithm used to compute PCs (the NIPALS method being very common).

An important function of factor analysis is to relate PCs (sometimes called *abstract factors*) to chemical factors that can be directly interpreted as illustrated in Figure 31.4. Each chemical factor could be regarded as a chemical compound in the spectroscopic mixture, which has various characteristics including a spectrum and a concentration profile as follows:

$$\mathbf{X} = \mathbf{C} \cdot \mathbf{S} + \mathbf{E} \qquad (31.4)$$

- **C** is the matrix consisting of the elution profiles of each compound and
- **S** is the matrix consisting of the spectra of each compound.

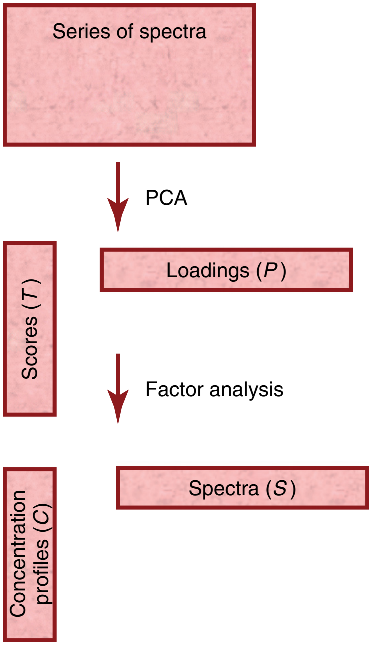

Fig. 31.4 Relationship between PCA and factor analysis.

31.2.3
How Many Components?

Normally, the first stage in factor analysis is the determination of the number of significant components in a series of mixture spectra. The number of significant PCs should be usually equal to the number of compounds in a mixture under most circumstances, although there may be problems. The first is if the concentration of two or more compounds are perfectly correlated, the number of significant PCs or factors will be less than the number of compounds in the mixture. For example, a reaction of the form A + B → C will appear to consist of two factors and not three because there are correlations between the reactants. The second is if there are additional effects such as due to variable baseline, temperature, instrumental drift, or significant noise levels, these could increase the apparent number of factors. There will always be some noise from an instrument; hence, even if there are, for example, four uncorrelated species in a mixture, a four-component model will not exactly fit the data, as there will be a small amount of error (matrix **E** above).

There are numerous methods for the determination of the number of significant components in a series of spectra. There are several groups of methods.

1. The first group of methods uses the size of each successive PC. This is measured by its eigenvalue, which is sometimes defined by the sum of squares of the scores. For each additional PC, the eigenvalue decreases. There are numerous approaches for determining the cut-off threshold, many of which have been developed and described by Malinowski (Malinowski, 2002).
2. The second group of methods is based on cross validation (Wold, 1978). These approaches involve removing one or more samples (or portions of the data) and using the rest of the samples to predict their properties. For example, if one performs PCA on 19 out of 20 spectra, one could determine the loadings of the data matrix using 19 samples. The score of the 20th sample could be predicted and this would then be used to estimate the spectrum of this sample and to see how close it is to the true spectrum. If the PCs are real PCs, they should model factors that are actually in the data, but if too many have been calculated, the later ones will be influenced primarily by noise and as such will provide poor prediction. The procedure is repeated until all the spectra are left out at least once. An optimum number of components will result in a minimum error.
3. The third set of approaches is based on the bootstrap (Efron and Tibshirani, 1993). This approach is not common in traditional spectroscopic data analysis because it is computationally intensive, but as computing power has become more cost effective and is more accessible, it is likely to be adopted more in the future. These methods involve removing several samples at a time, and then iteratively repeating this often a hundred times or more. The PC model is applied to the samples that remain each time and then tested on the samples that are left out. The number of components in the data is usually assessed by majority vote, for example, if the optimum is found to be 4 PCs in 85

out of 100 iterations, then this value is employed.

4. There are a number of techniques, such as orthogonal projection approach and SIMPLISMA (De Braekeleer and Massart, 1997; Windig *et al.*, 1992), and eigenvalue plots (Gampp *et al.*, 1985) that primarily rely on graphical inspection of data.

Then, this first step is used to determine the dimensions of the scores and loadings matrices. Hence, if the original data matrix has dimensions 30 × 1000 and if the number of significant PCs is denoted by A, then

- the dimensions of **T** will be $30 \times A$ and
- the dimensions of **P** will be $A \times 1000$.

The dimensions of **C** and **S** will be the same as **T** and **P**, respectively. Naturally, if the number of significant components is incorrectly estimated, then there can be problems with the reconstruction of the spectra and concentration profiles, but often this is evident visually.

31.2.4
Resolution

Once the number of components has been established, it is necessary to resolve the spectra into individual factors. One important principle behind most methods

$$\mathbf{X} \approx \mathbf{T} \cdot \mathbf{P} = \mathbf{C} \cdot \mathbf{S} \tag{31.5}$$

$$\mathbf{C} = \mathbf{T} \cdot \mathbf{R} \text{ and } \mathbf{S} = \mathbf{R}^{-1} \cdot \mathbf{P} \tag{31.6}$$

so to convert from scores to concentration profiles and from loadings to spectra, it is necessary to find a matrix **R** that is variously called a *transformation*, *rotation*, or *regression matrix*. This method is sometimes referred to as *principal components regression* (*PCR*). Alternatively, knowing **X** and either **C** or **S**, one can find the missing matrix, or if one has a guess of both **C** and **S**, it will be considered a good guess if one can predict **X** well.

There are a plethora of approaches that are summarized below.

31.2.4.1 Noniterative Methods

Many methods for resolution of mixtures involve finding selective variables for each compound: these could be specific wavelengths unique to each particular compound or specific points in time where one species (e.g., in a reaction mixture) is uniquely present. The first set of methods is where every component in a mixture contains some selective or unique information, which is used as a handle for factor analysis, and the second where there are some components without selective information.

Where all components have some selective information, the first step is to find selective or key variables for each component in the mixture. These could be found visually or it is possible to look at small regions (windows) in the mixture spectra and see which regions (if any) are characterized by one significant eigenvalue and thus are likely to correspond to the absorption of a single compound.

Once diagnostic variables have been found, the question is, what is the next stage? Multiple linear regression (MLR) is a common way to complete the picture. If concentration profiles are known (or can be approximated) using key variables such as m/z values, or wavenumbers, we can estimate the spectra by

$$\mathbf{S} \approx \mathbf{C}^{+} \cdot \mathbf{X} \tag{31.7}$$

where superscript + stands for the pseudoinverse.

Some more mathematically oriented chemometricians prefer PCR. There are several sophisticated algorithms in the literature, but a common basis of most of the approaches is to try to find a rotation, transformation, or regression matrix between the scores of a portion of the data and the known information. The first step involves performing PCA over the entire region of the spectra, and keeping a scores matrix **T** that has as many columns as compounds are suspected to be in the mixture. For example, if we know the pure spectral regions for each of the compounds, then we know their concentration profiles **C** from these regions and thus **R** and **S** can be estimated from the scores by

$$\mathbf{R} = \mathbf{T}^{+} \cdot \mathbf{C} \tag{31.8}$$

$$\mathbf{S} \approx \mathbf{R}^{-1} \cdot \mathbf{P} \tag{31.9}$$

Some PCA-based approaches are also called *evolving* (or *evolutionary*) *factor analysis*, but there is a significant terminology problem in the literature, as EFA also denotes the use of eigenvalue plots to determine how many components are in a mixture. There is a lot of history in the names chemometricians use for methods in this area, but the main thing is to keep a very cool head and understand the steps in each approach rather than become confused by the huge variety of names.

When only some components exhibit selectivity, the situation become slightly difficult. A typical example is a UV/vis spectrum of a mixture in which some of the compounds are buried within the spectra and do not have any characteristic wavelengths. Fortunately, PCA can be used here. There are several different ways of exploiting this. One approach uses the idea of a zero-intensity window. The first step is to determine regions for each compound where they are *not* present either in the spectrum or in the profile (e.g., pH profile). This information may be obtained from a number of approaches such as eigenvalue plots. In this region, we expect the intensity of the specific compound to be zero; hence, it is possible to find a vector **r** for each component so that

$$\mathbf{0} = \mathbf{T}_0 \cdot \mathbf{r} \tag{31.10}$$

where **0** is a vector of zeros, if the zero-composition region is for the samples, and $\mathbf{T}_0$ is the portion of the scores in this region. However, there is a problem, that is, one of the elements in the vector **r** must be set to an arbitrary number, usually the first coefficient is set to 1, but this does not have a serious effect on the algorithm. So long as there is always a region of the spectra or samples where at least one component in a mixture is absent, which can be identified, this procedure should always be possible to perform. If one is uncertain about the true number of compounds (or PCs), it is possible simply to change this and to see what happens with different guesses and see whether sensible results are obtained. The matrix **R** can be set up as mentioned above, and the estimated profiles of all the compounds are obtained over the entire region by $\hat{\mathbf{C}} = \mathbf{T} \cdot \mathbf{R}$ and the spectra by $\hat{\mathbf{S}} = \mathbf{R}^{-1} \cdot \mathbf{P}$.

31.2.4.2 **Iterative Methods**

The methods discussed in Section 31.2.4.1 are noniterative, that is, they have a single step that leads to a single solution. However over the years, chemometricians have refined these approaches to develop iterative methods that are based on many of the aforementioned principles but do not stop at the first solution and continue until the solution converges. These methods are particularly useful where only some analytes exhibit selective regions.

First, it is common to produce an initial estimate of the spectrum of each pure species in a series of mixture spectra. In equilibrium studies, there are often regions, for example, of pH, where one compound predominates or is uniquely present. One simple method is called the *needle* search. For each component in a mixture, the datapoints of maximum purity are taken as the initial guesses of the spectra of each component; these are simply spikes at the first stage, that is, one spike for each component: remember that when studying mixtures there may not be any samples that are characteristic of just one compound (e.g., a point in time of reaction mixture), but nevertheless there will be regions of maximum purity for each component in the mixture. Methods such as eigenvalue plots, OPA, and SIMPLISMA can be employed to find these regions, each pure variable being the starting guess of each component. None of these approaches are likely to provide perfect estimates of the spectra and result in initial estimates or guesses.

A feature of most of these methods is that different criteria can then be employed to assess the desirability of the model. Alternating least squares (ALS) (Tauler, Kowalski and Fleming, 1993) is a popular choice. Consider estimating, perhaps imperfectly, the above-mentioned spectra. We can now estimate, in turn, the concentration profiles by

$$\mathbf{C} = \mathbf{X} \cdot \mathbf{S}^{+} \tag{31.11}$$

If a good model is obtained, the concentration profiles should obey certain properties: the most common is nonnegativity, but other constraints can be imposed such as unimodality if desired, especially if there is some knowledge of the equilibrium process. Hence, **C** is altered and a new estimate of **S** can be obtained using these modified versions of concentration profiles and so on, until both **C** and **S** obey the constraints and they are stable (i.e., do not change much each iteration), to get a final solution. The method can be turned on its head in that instead of first guessing pure spectra it is also possible to first guess pure concentration profiles, and then following similar steps, usually iteratively, to obtain a correct solution.

Iterative target transform factor analysis (ITTFA) (Vandeginste, Derks and Kateman, 1985) is an alternative approach used to improve these guesses. PCA is performed first on the dataset, and a rotation or transformation matrix **R** is found to relate the scores to the first guesses of the spectra, just as mentioned above. This, in turn, allows the spectra to be predicted. However, the next stage is the difficult part. The predicted spectral matrix $\hat{\mathbf{S}}$ is examined. In the initial stages, this matrix will usually contain elements that are not physically meaningful, for example, negative regions. These negative regions are changed, normally by the simple procedure of substituting the negative numbers by zero, to provide new estimates of the spectra. This, in turn, results in fresh estimates of the elution profiles that can then be corrected for negativity and so on. This iteration continues until the estimated concentration profiles **C** show very little change. The performance of ITTFA depends on the quality of the initial guesses, but can be an effective algorithm. Nonnegativity is the most common condition, but other constraints can be added.

ALS is based on similar principles, but the criterion for convergence is slightly different and looks at the error between the reconstructed data from the product of the estimated concentration profiles and spectra ($\mathbf{C} \cdot \mathbf{S}$) and the true data. In addition, implemented guesses of either the initial spectra or concentration profiles can be used to start the iterations, whereas for ITTFA it is normal to start with the concentration profiles. The ALS procedure is often considered slightly more general and ITTFA was developed very much with analytical applications in spectroscopy coupled to chromatography or another technique, whereas the idea of ALS was borrowed from general statistics. In practice, neither method is radically different, the main distinction being the stopping criteria.

31.2.4.3 Combining Information

Often different types of information can be combined, for example, we may know the order of a reaction and may want to combine known kinetics with multivariate information, rather than treat each type separately.

There are a wide variety of ways to combine both types of information, but most involve using two alternating criteria. Consider knowing the pure spectra of the reactants and products, as well as the starting material. We can then "guess" a value of k (the rate constant), which gives the profiles of each compound in the mixture, often represented by the matrix **C**. We can then use this to "guess" a value of the original data matrix **X** since $\mathbf{X} \approx \mathbf{C} \cdot \mathbf{S}$ or, in other words, the observed reaction spectra are the product of the concentration profiles and pure compound spectra. If our estimated rate constant is accurate, then the estimate of **X** is quite good. However, if this is not very accurate, we need to change our rate constant, change the profiles, and continue until we get a good fit.

This theoretically simple approach takes into account both the "hard" kinetic models used to obtain **C** and the "soft" spectroscopic models used to see how well the estimated spectra equal the observed spectra. Life, though, is never so simple. We may not know the spectra of every compound perfectly, and certainly not in a quantitative way, we may be uncertain of the starting concentrations, and there may be unknown impurities or some side reactions. Hence, many sophisticated elaborations of these approaches have been proposed involving changing several parameters simultaneously including the initial concentrations.

PCA also can be incorporated into these methods via PCR. If we know the scores **T** of the data matrix and guess **C** using our kinetics models, then we can find a transformation matrix $\mathbf{R} = \mathbf{T}^{+} \cdot \mathbf{C}$. Now we can see how well the scores are predicted, using matrix **R** and adjust k (and any other parameters) accordingly and continue in an iterative way. The most common techniques used are ALS and ITTFA, which been already been introduced, although several tailor-made elaborations have been developed specifically for reaction monitoring.

Kinetics knowledge is not the only information that can be obtained about a series of spectra and these models are by no means restricted to kinetics. There are many other constraints that can be incorporated. Simple ones are those where spectra and concentration profiles are positive, but more elaborate ones can be incorporated. For example, concentration profiles with time are likely to be smooth and unimodal; the profile of the starting materials will decrease with time and for all other compounds it can increase and then sometimes decrease. These can all be incorporated into algorithms, allowing the models to contain as many constraints as required, although the convergence of the algorithms can be quite tricky if a large number of factors are taken into consideration.

31.3
Calibration

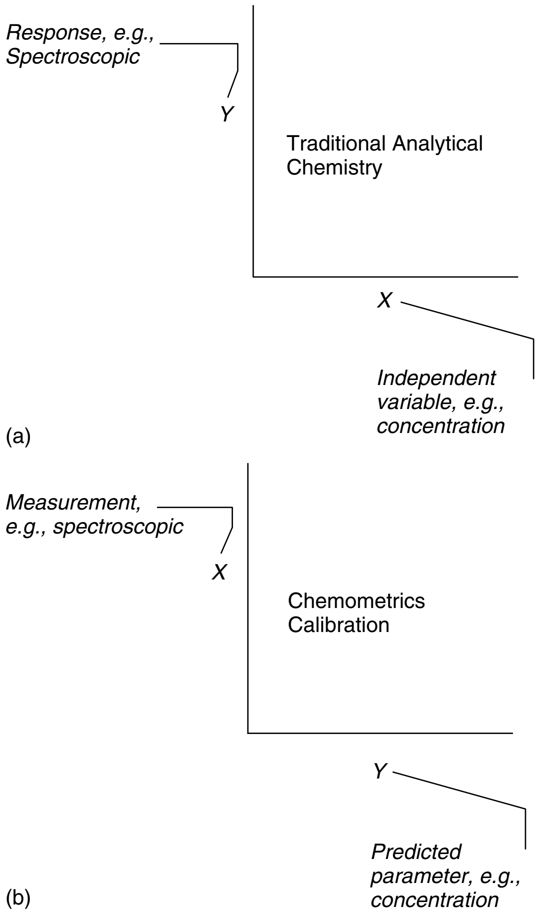
Calibration plays an important role in spectroscopy. It involves using a spectral response to predict the concentrations or characteristics of individual components. In chemometrics or analytical chemistry, the calibration problem is often formulated as an *inverse* problem. For example, it is often important to be able to predict a concentration from a spectrum. In classical physical chemistry, often the problem is reversed; for example, can we predict a rate constant from a temperature and thus understand the causal relationship between temperature and observed kinetics? In analytical chemistry, the rate constant could be used as a type of thermometer to predict a temperature, rather than vice versa. In addition, there is a notation difference between traditional analytical chemistry and chemometrics, as illustrated in Figure 31.5, where the x variable, in chemometrics, normally represents spectroscopic data, and the y variable represents a predicted property, often the concentration of a compound in a mixture.

To clarify this, we use c as the property to be predicted and x as the data measured to predict this property, usually spectra; hence, the aim of calibration is to predict c from x. The spectroscopy data is called the *x block* and the concentration (or other properties) that is to be deduced from the spectra is called the *c block*.

Note that although the aim of calibration is to predict, for example, the concentrations of compounds in a spectroscopic mixture, there are usually two stages. The first one is calibration or modeling, which uses a set of samples of known composition to form a relationship between the spectral characteristics and the composition or other properties of the mixture. The second one is called *prediction* where the calibration model is used to predict the composition of unknown samples. A recent review discusses calibration in greater detail (Brereton, 2000) and the text by Martens and Næs (Martens and Næs, 1989) is a classic in the subject.

31.3.1
Univariate Calibration

The most traditional, but still very widely used, method of calibration in chemistry is univariate, involving calibrating a



Response, e.g., Spectroscopic
Y
Traditional Analytical Chemistry
X
Independent variable, e.g., concentration
(a)
Measurement, e.g., spectroscopic

single variable (e.g., a spectroscopic intensity) to another variable (e.g., a concentration). The literature goes back a century; however, with the ready availability of matrix-based computer packages ranging from spreadsheets to more sophisticated programming environments such as Matlab, we can approach this area in new ways.

31.3.1.1 **Classical Calibration**

Most chemists are familiar with this approach. An equation of the form

$$x = bc \tag{31.12}$$

is obtained relating, for example, a spectroscopic intensity to a concentration. Sometimes an intercept term is introduced:

$$x = b_0 + b_1 c \tag{31.13}$$

and it is also possible to include squared and higher order terms.

There are several difficulties with classical methods. First, the aim of calibration is to predict c from x and not vice versa: the classical method involves obtaining a model x from c; it may be what a physical chemist wants but not necessarily what an analytical chemist wants to do. The second, and more serious, difficulty is that the greatest source of error is generally in the preparation of sample; hence, the measurement of a concentration (even when determining a calibration model) is likely to be less certain than the measurement of spectral intensity. Twenty years ago, many instruments produced less reproducible results than now, but the significant increase in instrumental performance has not been accompanied by an equally significant improvement in the quality of measurement cylinders, pipettes, and balances.

31.3.1.2 Inverse Calibration

An alternative approach is to assume that the errors are in the c block. This means fitting an equation of the form

$$c = ax \tag{31.14}$$

or

$$c = a_0 + a_1 x \tag{31.15}$$

In terms of both error analysis and scientific motivation, this is more rational than by employing classical calibration, but most chemists still use classical methods even though they are often less appropriate.

If, however, a calibration dataset is well behaved and does not have any significant outliers, straight lines obtained using both forms of calibration should be roughly similar, as illustrated in Figure 31.6. Sometimes there are outlying points, which may come from atypical or erroneous samples, and these can have considerable influence on the calibration lines and there are many technical ways of handling these outliers, which are often said to have high leverage: generally the two types of best fit straight line are influenced in different ways, and this discrepancy can be eliminated by removing any outliers.

31.3.1.3 Determining the Relationship between Variables

Instead of deriving quite complex equations, it is easier to obtain best fit

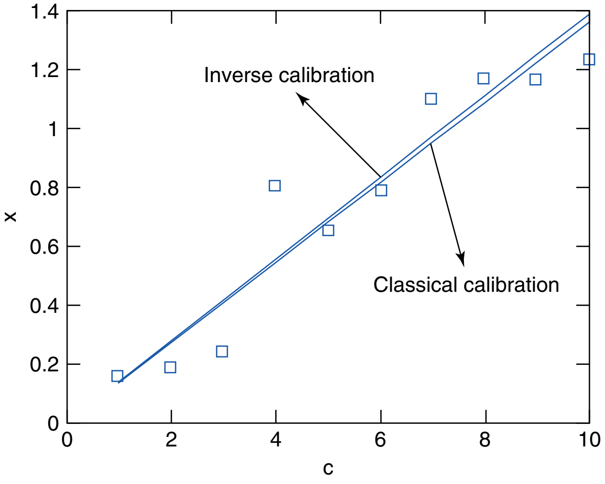

Fig. 31.6 Classical and inverse calibration lines.

calibration parameters using simple vector arithmetic. For inverse calibration, we can use the left pseudoinverse; hence,

$$a \approx (\mathbf{x}' \cdot \mathbf{x})^{-1} \cdot \mathbf{x}' \cdot \mathbf{c} = \mathbf{x}^{+} \cdot \mathbf{c} \qquad (31.16)$$

where **x** is a vector of spectroscopic responses (often peak heights at a single wavelengths) and **c** is the corresponding concentrations. Note that $(\mathbf{x}' \cdot \mathbf{x})^{-1}$ is actually a scalar or a single number in this case, equal to the inverse of the sum of squares of the elements of **x**.

Sometimes it is desirable to include an intercept (or baseline term) of the form

$$c = a_0 + a_1 x \qquad (31.17)$$

Now the power of matrices and vectors becomes evident. Instead of using a single column vector for **x**, we use a matrix whose first column consists of ones and second of the experimentally determined x values, and **a** becomes a row vector of two elements, each element being one coefficient in the equation. The equation can now be expressed as

$$\mathbf{c} = \mathbf{X} \cdot \mathbf{a} \qquad (31.18)$$

so that

$$\mathbf{a} \approx \mathbf{X}^{+} \cdot \mathbf{c} \qquad (31.19)$$

31.3.2
Multiple Linear Regression

MLR is one of the commonest techniques for calibration and regression both in chemistry and statistics.

In the context of the spectroscopy of mixtures, the principle is that a series of mixture spectra can be characterized by

- the spectrum of each individual component;
- the concentrations of these components; and
- noise (or experimental error).

Mathematically, this information can be expressed in a matrix format:

$$\mathbf{X} = \mathbf{C} \cdot \mathbf{S} + \mathbf{E} \qquad (31.20)$$

This equation has already been discussed in Section 2.2. The **X** matrix might, for example, consist of a series of uv spectra of a reaction of the form

$$\mathrm{A} \rightarrow \mathrm{B} + \mathrm{C} \qquad (31.21)$$

consisting of three compounds whose concentrations we wish to monitor as a function of time. Each spectrum will be a row of the matrix **X** and each corresponding row of **C** will consist of concentrations of each component in the reaction mixture at a specific sampling time.

To study the reaction, it is usually necessary to determine **C**. There are many ways of using MLR to obtain this information. The simplest is not really calibration, but involves knowing the spectra of a unit concentration of each pure component, **S**. Using the pseudoinverse, we can write

$$\mathbf{C} \approx \mathbf{X} \cdot \mathbf{S}^{+} \qquad (31.22)$$

However, this supposes that we can actually obtain the spectra of all components in a mixture, that we know all the components and have isolated them, and also that the conditions in the reaction mixture are similar to those of the pure components. An alternative is to take some mixtures, quench them (where necessary), and then measure the concentrations of the components using an off-line method such as chromatography, where each is separable and peak areas can easily be related to the concentration as illustrated in Figure 31.7. We can then determine and estimate $\hat{\mathbf{S}}^{+}$ from this training or calibration set, where the notation "^" means predicted rather than observed, as we know $\mathbf{C}$ from the off-line chromatographic peak areas. This can be used to set up a calibration model and in the future predict the concentrations of compounds from their spectra in the absence of chromatography. If we are satisfied with the calibration model, we can then predict the concentrations in the reaction mixture

$$\hat{\mathbf{C}} = \mathbf{X}_{\text{reaction}} \cdot \hat{\mathbf{S}}^{+} \qquad (31.23)$$

and thus obtain the profiles of each compound with time.

MLR can be extended to include nonlinear such as with squared terms, which can be useful under some circumstances, for example, if there are nonlinearities due to overloaded spectra (which may occur if concentrations in a reaction mixture, for example, are outside the region where the Beer–Lambert law is obeyed). Extra columns are simply added to the $\mathbf{X}$ matrix equal to squares of the intensities. Another common modification is weighted regression, where certain wavelengths have more significance than others.

However, MLR has the disadvantage that all significant compounds in a mixture should be known. If we have information on two out of five compounds in a series of spectra, then the two predicted spectra will also contain features of the spectra of the remaining three compounds, distributed between the two known components (dependent on the nature of the calibration set) and the concentration estimates will contain large and fairly unpredictable errors. It is sometimes possible to overcome this problem if there are selective wavelengths where only two compounds absorb, so that the $\mathbf{X}$ matrix consists of only certain selective regions of the spectrum; however, there are alternative approaches, discussed later, where good models can be obtained using information when only a proportion of the compounds in a mixture can be characterized.

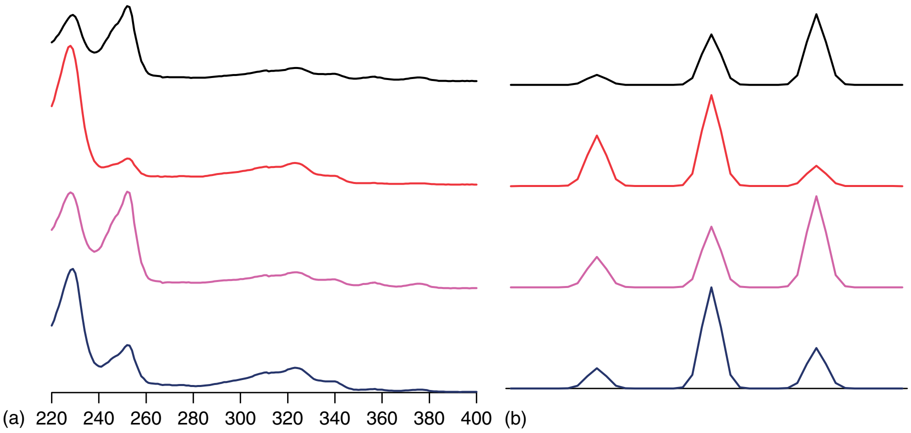

Fig. 31.7 Calibrating spectra (a) to chromatograms (b).

31.3.3
Principal Components Regression

Some consider PCR as a form of factor analysis. Although the two concepts are interchangeable according to some chemometricians, especially spectroscopists, it is important to recognize that there are widespread differences in the usage of the term *factor analysis* by different authors, groups, and software vendors.

PCR has a major role in the spectroscopy of mixtures. It is most useful where only some compounds can be identified in the mixture. For example, we may be interested in the concentration of a carcinogenic chemical in a sample of seawater, but have no direct knowledge or interest in the identities and concentrations all the other chemicals. Can we determine this by spectroscopy of mixtures? MLR works best when all the significant components are identified.

The first step, as always, is to obtain a series of spectra (the calibration or training set), for example, the UV spectra of 30 samples recorded at 200 wavelengths, represented by a 30 × 200 matrix **X**. The next step is to perform PCA as discussed in Section 31.2.2 to obtain scores and loadings matrices, **T** and **P**. A crucial decision is the determination of the number of PCs that should be retained (Section 31.2.3). Ideally, this should equal the number of compounds in a mixture. For example, if there are seven compounds we should retain the first seven PCs, so that the matrix **T** is of dimensions 30 × 7 and **P** of dimensions 7 × 200, in this context. However, in real-world situations, this information is rarely known exactly. In many cases, the number of PCs needed to model the data is very different from the number of real components in a series of mixtures. This is because of correlations between compound concentrations, spectral similarities, and experimental design that often reduce the number of components, and noise and instrumental features such as baseline problems that may increase the number of components.

The next step is variously called *regression, transformation,* or *rotation.* A common approach is to find a relationship between the scores and the true concentrations of a compound of the form

$$\mathbf{c} = \mathbf{T} \cdot \mathbf{r} \tag{31.24}$$

where **c** corresponds to the known concentrations in the mixture spectra and **r** is the column vector whose length equals the number of PCs (seven in this example). This is represented diagrammatically in Figure 31.4. Equation (31.24) can also be expressed as follows:

$$c = t_1 r_1 + t_2 r_2 + \cdots + t_7 r_7 \tag{31.25}$$

if there are seven PCs, where t_1 is the score of the first PC, and r_1 is its corresponding coefficient obtained using regression.

Knowing **c** and **T**, it is not very difficult to estimate **r** using the pseudoinverse by

$$\mathbf{r} = \mathbf{T}^{+} \cdot \mathbf{c} \tag{31.26}$$

This permits the concentration of an individual compound to be estimated by knowing the scores.

If there are several compounds of interest, it is a simple procedure to expand "*c*" from a vector to a matrix, each column corresponding to a compound, so that

$$\mathbf{C} = \mathbf{T} \cdot \mathbf{R} \tag{31.27}$$

As usual, we can determine **R** by

$$\mathbf{R} = \mathbf{T}^{+} \cdot \mathbf{C} \tag{31.28}$$

The extreme case is when the number of PCs is exactly equal to the number of known compounds in the mixture, in which case **R** becomes a square matrix.

The quality of prediction is then demonstrated on a test set (see Section 31.3.5) and finally the method is used on real data of unknowns. It is also useful to be able to preprocess the data under certain circumstances before PCA. This process often involves mean centering or standardizing the spectral matrix before PCA, rather than using the raw spectroscopic data, for example

$$x_{ij} = \frac{x_{ij} - \overline{x}_j}{s_j} \tag{31.29}$$

where x_{ij} is the spectroscopic intensity in spectrum i and wavelength j, $\overline{x}_j$ is the mean intensity over all spectra in the calibration set at wavelength j, and s_j is the corresponding standard deviation: this is valuable if it is desired to weight all wavelengths to be of equal significance, which is often useful in techniques such as NIR and UV/vis where PCR represents a significant improvement over MLR when only partial information is available about the number of components in a mixture, as one can have as many or as few components in the regression model as desired, so long as the number of PCs is determined well.

31.3.4
Partial Least Squares

PLS has a long history in chemometrics. This technique was originally proposed by the Swedish statistician, Herman Wold, whose interests were primarily in economic forecasting. In the 1960s his son Svante Wold, together with a number of Scandinavian scientists, advocated its use in chemistry. Possibly no technique in chemometrics is so mired in controversy, with some groups advocating PLS for almost everything (including classification) with numerous extensions over the last two decades, with other groups agreeing that PLS is useful, but one of very many techniques in the toolbox of the chemometrician. Probably, one confusion is between the availability of good software (there is currently some excellent public domain software for PLS) and the desirability (independently of software) for using PLS. In many areas of calibration, PCR serves almost the same purpose; however, despite this, PLS has been the subject of more extensions and articles than probably any other chemometrics method, and there is a large hard-core of believers who solve most problems (usually quite successfully) by PLS. An important early review of the method was published by Geladi and Kowalski in 1986 (Geladi and Kowalski, 1986).

One principle guiding PLS is that modeling the c block of data is as important as modeling the experimental x information. A drawback of PCR is that the PCs are calculated exclusively on the x block and do not take into account the c block. In PLS, components are obtained using both x and c data simultaneously. Statisticians like to think about modeling covariance as opposed to variance. Most conventional least squares approaches involve finding a variable that maximizes the value of x^2 or the square of the modeled experimental data or variance. PLS finds a variable that maximizes xc or the product of the modeled experimental data with the concentrations, often called the *covariance*. In physical terms, PLS assumes that there are errors in both types of information, which are of equal importance. This makes some sense: the concentrations used in calibration are subject to error (e.g., dilution and weighing) just as much as the spectra or chromatograms. MLR and PCR as commonly applied in chemistry assume that all the errors are in the spectroscopic data and that the concentrations in the calibration set are known exactly.

Often PLS is presented in the form of two equations. There are a number of ways of expressing these, a common one being

$$\mathbf{X} = \mathbf{T} \cdot \mathbf{P} + \mathbf{E} \tag{31.30}$$

$$\mathbf{c} = \mathbf{T} \cdot \mathbf{q} + \mathbf{f} \tag{31.31}$$

as illustrated in Figure 31.8. Equation (31.30) appears to be similar to that of PCA, but the scores matrix also models the concentrations, and the vector $\mathbf{q}$ has some analogy to a loadings vector. The matrix $\mathbf{T}$ is common to both the equations. $\mathbf{E}$ is an error matrix for the x block and $\mathbf{f}$ an error vector for the c block. The scores are orthogonal, but the loadings ($\mathbf{P}$) are not. There are various algorithms for PLS, and in many the loadings are not normalized. PLS scores and loadings differ numerically from PCA scores and loadings and are dependent both on experimental measurements (e.g., spectra) and the concentrations or properties of the spectral matrices. In PCA, the scores and loadings depend only on the spectra or x block. In PLS, the product $\mathbf{T} \cdot \mathbf{P}$ does not provide the best fit estimate of the x block. The size of each successive component (as assessed by the sum of squares of each successive vector in $\mathbf{T}$) does not always decline; later vectors may be larger than earlier ones, unlike in PCA. In addition to matrices $\mathbf{T}$ and $\mathbf{P}$ in PLS, there is another matrix called a *weights matrix* $\mathbf{W}$ which is often used, which has analogies to the $\mathbf{P}$ matrix and is a consequence of the algorithm. Some like to use $\mathbf{W}$ instead of or in addition to $\mathbf{P}$. In the PLS literature, it is quite important to read quite closely each paper and determine precisely which algorithm is being employed, there being a much wider range of terminology than in PCA.

The quality of the models can be determined by the size of the errors,

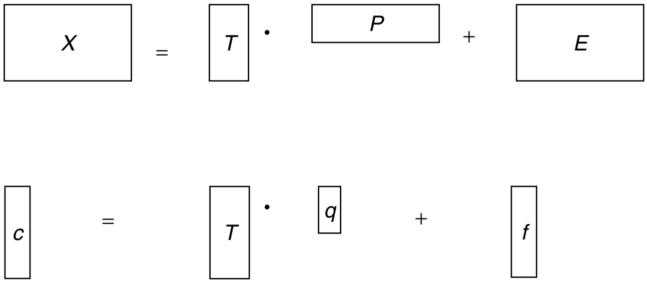

Fig. 31.8 PLS principles.

normally the sum of squares of **E** and **f** is calculated. The number of significant PLS components can be estimated based on these errors, often using cross validation or the bootstrap, although it can be done on the training set (often called *autoprediction*) as discussed in Section 31.3.5. It is important to recognize that there are a large number of criteria for determining the number of significant components that can cause major disagreements between packages and different algorithms.

There are several extensions to PLS.

The standard algorithm described above is sometimes called *PLS1*. One extension, first proposed in the 1980s, is *PLS2* (Hoskuldsson, 1988). In this case, the concentration (or c) block consists of more than one variable, an example being a case in which there are three components in a mixture and hence **C** becomes a matrix with three columns, and Eq. (31.31) changes to

$$\mathbf{C} = \mathbf{T} \cdot \mathbf{Q} + \mathbf{F} \tag{31.32}$$

In analytical spectroscopy, PLS2 is not very popular and often gives worse results than PLS1. However, if there are interactions between variables that correspond to the columns of **C**, this method can have advantages. In most cases in analytical chemistry, however, mixture spectra or chromatograms are linearly additive and independent. An original advantage of PLS2 was also that it was faster in performing several PLS1 calculations, but with modern computing power this is no longer serious.

Another common extension is to include nonlinear (in most case squared) terms in the PLS equation. This is very similar in effect to extending MLR models by including extra terms. Often, however, if a problem is highly nonlinear, completely different approaches such as neural networks may be more appropriate for calibration.

PLS has advantages over MLR in that only some of the components need to be known and over PCR in that the errors can be in both the x and c blocks, and is particularly good when the aim is to determine a statistical or bulk measurement, for example, the amount of wheat in protein. In Section 31.3.5, validation of the models is discussed in more detail. However, if all the components in a mixture are known and are linearly additive, more conventional approaches such as MLR may perform equally well or even better.

31.3.5
Model Optimization and Validation

One of the most important problems in the area of multivariate calibration is determining its effectiveness. The main aim of the model is to use a mathematical function of experimental data to predict a parameter such as concentration. In PCR and PLS, we have to choose the number of components to be retained in the model, which represent one of the dimensions (A) of the scores and loadings matrices. The size of these matrices influences the quality of predictions.

There are two objectives of these methods. The first is to optimize the model and thus determine the optimum number of components (in PLS and PCR). The second is to have an independent assessment about its performance. Often these two aims are mixed up and many people in the area of calibration just cite the calibration and prediction error, the latter being obtained while optimizing the model. We have discussed several approaches in the context of PCA (Section 31.2.3) and briefly introduce this in the context of calibration.

Autoprediction involves looking at the residual, often root mean square, error of calibration. This can be calculated

$$RMSEC = \frac{\sum_{i=1}^{I}(c_i - \hat{c}_i)^2}{D} \qquad (31.33)$$

for the c block, where D is defined as the number of degrees of freedom, which is usually $I-A$, where A is the number of components, I is the number of samples in the calibration or training set, and $\hat{c}_i$ is the predicted value for the tth sample. If the columns are centered, $D = I - A - 1$. This usually decreases the more the variables but the number of components that result in a percentage threshold for the residual error such as 5% could be established for the number of significant PCs. There are variants on this including using the x block, in the literature.

For cross validation (Wold, 1978), similar equations can be established except that the divisor is I, the number of samples rather than the number of degrees of freedom. The root mean square of cross validation (RMSECV) should reach a minimum when the correct number of components is determined. Similar types of equations can be obtained using the bootstrap (Efron and Tibshirani, 1993), likewise searching for a minimum. In both the cases, sometimes there are problems with flat minima or noisy minima that do not have an obvious optimum, and various elaborate rules are available for choosing the number of components to be employed in the model. Both these errors (from cross validation and the bootstrap) should be larger than the autopredictive error.

An external test set is often employed to determine the model performance. This involves samples that have not been used for optimization and have no influence on the number of components in the model, which gives the root mean square error of prediction (RMSEP). Ideally the RMSEP and RMSECV should be calculated on completely different data as one is about using an independent test set to validate the model and the others to optimize the model. Usually $RMSEC < RMSECV < RMSEP$, although there can be exceptions to the rule in unusual situations.

There are several other elaborations to optimizing and validating the models, according to the author and software package, and it is usually important to understand how this is done: most packages are based on different philosophies. However, the above-mentioned methods are some of the most common.

31.4
Exploratory Methods

The approaches in Sections 31.2 and 31.3 aim primarily at determining characteristics of components primarily in a mixture, for example, the concentrations of individual compounds in a series of spectra or the spectra of these components. However, there are other reasons for employing chemometrics in spectroscopy.

Exploratory data analysis involves determining whether spectra form groups or are related. For example, it might be possible to determine the MIR spectra of extracts of the urine of patients with and without a disease and to see if these cluster differently and thus explore whether there are differences and why.

31.4.1
Principal Components Analysis

The most widespread methods are based on PCA. We have already described the theory in Section 31.2.2. In the context of calibration or resolution, the numerical values of the PCs are used to determine physical properties of components in a mixture.

In exploratory data analysis, the main aim is to determine whether spectra fall into groups and why. Most of the output is in the form of graphs. We illustrate this in an example from atomic spectroscopy in which the concentrations of 11 elements obtained using atomic spectroscopy are measured for 58 types of pottery (Bruno *et al.*, 2000) from two origins (or groups). The aim is to determine whether the atomic spectroscopic data can be used to distinguish the pottery and if so which elements are most characteristic of each group.

The first step is normally preprocessing, which involves putting the data on a sensible scale. There are several common procedures.

1. *Using the raw data without any preprocessing*: If all the spectra are roughly on the same scale and the amount of sample in each analysis is similar, this is acceptable. However, usually some additional steps are necessary.
2. *Row scaling*: If the amount of sample to be analyzed is difficult to control, then summing the rows to a constant total by ${}^{\text{nor}}x_{ij} = \frac{x_{ij}}{\sum_{j=1}^{J} x_{ij}}$ is a common procedure.
3. *Mean centering*: Often the columns (variables) are mean-centered. There is no inherent requirement to do this, but the majority of statistical packages perform this automatically as PCA often looks at variation around a mean.
4. *Standardizing*: If all the variables are on quite different scales, then this procedure is quite important. For example, some peaks may be small, but their variation is significant relative to large peaks. This is done by

$$ {}^{stn}x_{ij} = \frac{x_{ij} - \overline{x}_j}{\sqrt{\sum_{i=1}^{I} (x_{ij} - \overline{x}_j)^2 / I}} \qquad (31.34) $$

Note that mean centering and standardizing must be performed after any row scaling. The disadvantage with standardizing is that if there are noisy regions of a spectrum where there is no real information, these will degrade the model. This can be overcome in various ways, for example, by variable selection just keeping useful regions of the spectrum or by an offset on the bottom of the equation.

For the example in this section, we only show the results of standardizing the data.

The scores plot involves plotting the scores of one PC against an other (or in three dimensions three PCs against each other), or in algebraic terms, different columns of **T** against each other. These are represented in Figure 31.9. It can be seen from inspection that there are likely to be groupings. When plotting the scores there are lots of options, for example, any set of PCs can be chosen. Usually, the most significant ones (with the largest eigenvalues) are chosen, but

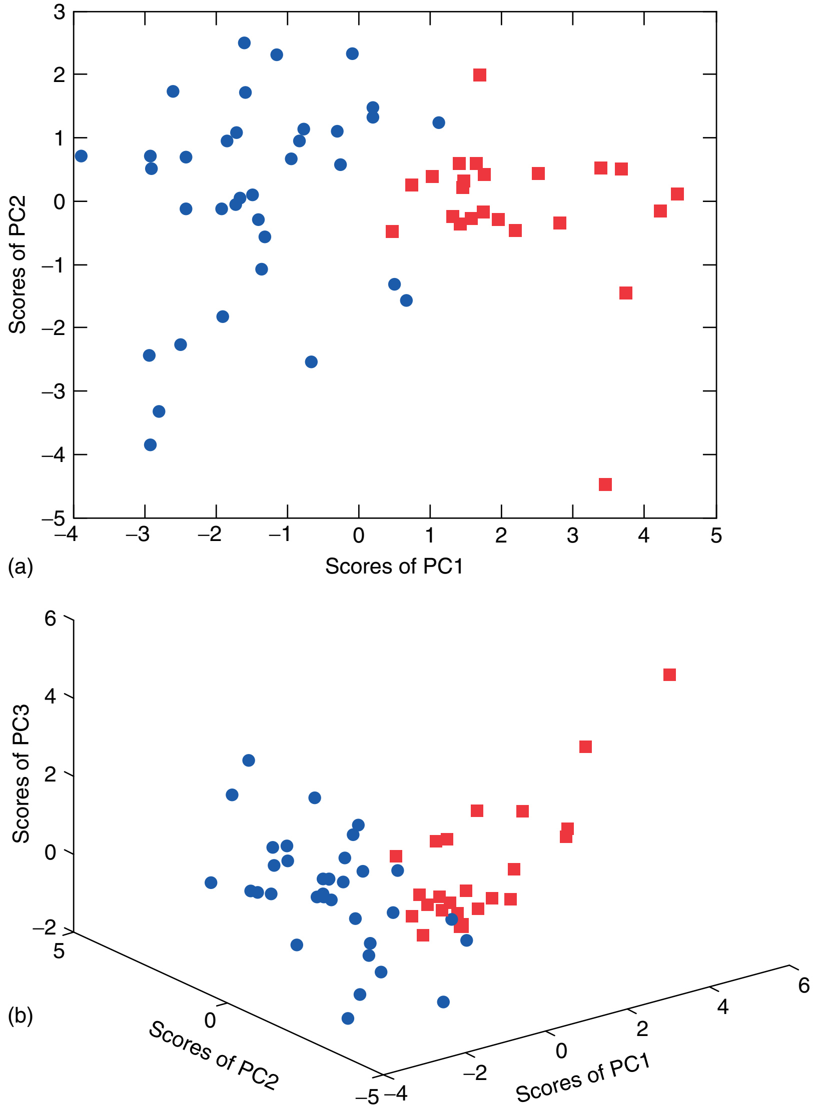

Fig. 31.9 A PC scores plots in which there are two groups in a dataset, in both two (a) and three dimensions (b).

sometimes smaller PCs are important for discriminating between samples, as the largest ones just provide overall information about the data. Often the most suitable PCs can be selected by graphical inspection of various plots.

Parallel to the scores plots are the loadings plots. These involve plotting the rows of **P** against each other, exactly analogous to the scores plots. A loadings plot is illustrated in Figure 31.10 for our example. We can see several features.

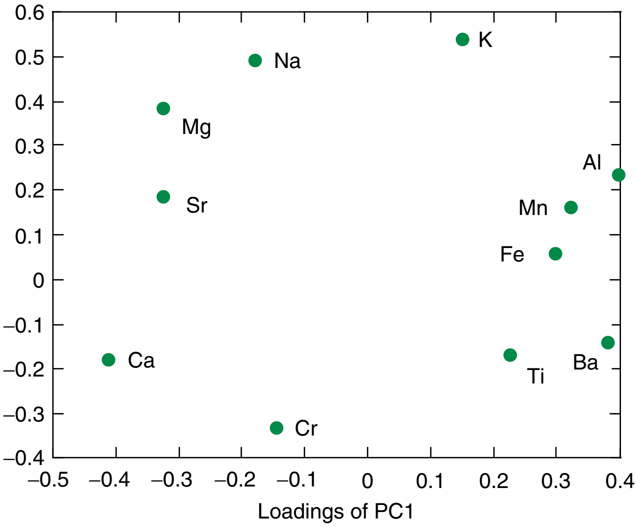

Fig. 31.10 Loadings of the elements corresponding to the example in Section 31.4.1.

The first is that some elements are clustered close together, meaning that they behave in a similar way, for example, Na and Mg. This basically means that if Na is found in high quantities so is Mg, and probably they come from the same source. The second is that one can compare the scores plot, for example, elements on the right-hand side are associated with the group represented by red squares; hence, Al and Mn are likely to be markers for this group of samples, that is, observed in high abundance.

The loadings can be of different forms, such as wavelengths in a spectrum, and would indicate the spectral features associated with specific groups of samples, for example, there may be groups of patients with and without a disease, and if these are separated in a scores plot, the corresponding loadings plot will tell whether there are spectral features diagnostic of specific groups of patients. When comparing scores and loadings plots, it is necessary to ensure that the same PCs are used in each case and that the preprocessing is the same.

PCA is not only used to see groupings but could also be used to see whether there are similarities between samples without any firm groupings, for example, whether there are outliers or whether samples taken as a function of time change with time. There are numerous graphical methods for presenting information about PCs of which the types of graphs, in this section, are the most popular.

31.4.2
Cluster Analysis

Exploratory data analysis, such as PCA, is used primarily to determine general relationships between data (Massart and Kaufmann, 1983; Everitt, Landau and Leese, 2001). Sometimes more complex questions need to be answered, such as, which samples are more similar to each other? Cluster analysis is a well-established approach that was developed primarily by biologists to determine similarities between organisms. Numerical taxonomy emerged from a desire to determine relationships between different species, for example, genera, families, and phyla. However, the spectroscopists also wish to relate samples in a similar manner. Which samples measured by spectroscopy are similar? Cluster analysis involves using a number of methods to group different samples (or objects) using chemical measurements such as spectroscopic intensities or peaks.

The first step is to determine the similarity between spectra. Often the spectra may need to be preprocessed before these distances are measured, for example, standardized, and the results depend on how the data are treated before cluster analysis, just as in the case of PCA.

A number of common numerical measures of similarity are available.

1. *Correlation coefficient between samples*: A correlation coefficient of 1 implies that the spectra have identical characteristics. This value will vary between −1 and +1.
2. *Cosine distance*: This measure involves determining one minus the cosine between the two spectra (treated as vectors).
3. *Euclidean distance*: The distance between spectra k and l is defined as

$$d_{kl} = \sqrt{\sum_{j=1}^{J}(x_{kj} - x_{lj})^2} \qquad (31.35)$$

   where there are j measurements, and x_{ij} is the jth measurement on the sample i, for example, x_{23} is the third wavelength of the second spectrum in a series. The smaller this value, the more similar the spectra; thus, this distance measure works in an opposite manner to the correlation coefficient.
4. *Manhattan distance*: This is defined slightly differently to the Euclidean distance and is given as

$$d_{kl} = \sum_{j=1}^{J} |x_{kj} - x_{lj}| \qquad (31.36)$$

Once a distance measure has been chosen, a similarity (or dissimilarity) matrix can be drawn up. This consists of a symmetric matrix whose dimensions are equal to the number of samples. In a dataset of I samples, the matrix will have dimensions $I \times I$ and is illustrated in Figure 31.11.

The next step is to link the objects. The most common approach is called *agglomerative* clustering, whereby single objects are gradually connected to each other in groups.

- From the raw data, find the two most similar objects.
- Next form a "group" consisting of the two most similar objects. The original I objects are now reduced to $I - 1$ groups.
- It is difficult to decide how to represent this new grouping. There are quite a few approaches, but it is common to change the data matrix from one consisting of six rows to a new one of five rows, four corresponding to original objects and one to the new group. The numerical similarity values between this new group and the remaining objects have

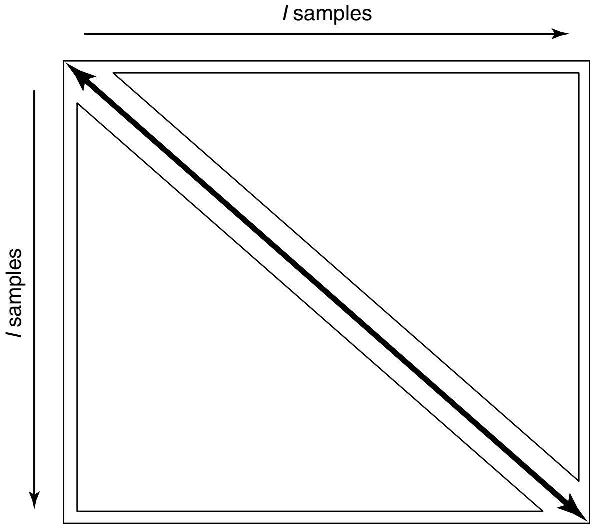

Fig. 31.11 (Dis)similarity matrix produced during cluster analysis. The diagonal values represent maximum similarity (or minimum dissimilarity) and the matrix is symmetrical.

to be recalculated. There are three principal ways of doing this.

1. *Nearest neighbor*: The similarity of the new group from all other groups is given by the *highest* similarity of either of the original objects to each other object.
2. *Farthest neighbor*: This is the opposite to nearest neighbor, and the *lowest* similarity is used.
3. *Average linkage*: The average similarity between two groups is used. There are, in fact, two different ways of doing this, differing according to the size of each group. For the raw data, we compare a group consisting of two members to one consisting of a single object; hence, the calculation is easy. However, in later steps we may want to combine a group consisting of two members with one of four members, and the two methods for calculating similarity indices differ if the number of objects in each group is also different.

The next steps consist of continuing to group the data just as above, until only one group, consisting of all the original objects, remains. It is normal to then determine at what similarity measure each object joined a larger group, and thus which objects resemble each other most. Often the result of hierarchical clustering is presented in a graphical form called a *dendrogram*: note that many biologists call this a *phylogram* and it differs from a cladogram where the size of all the branches are the same. The objects are organized in a row, according to their similarities: the vertical axis represents the similarity measure at which each successive object joins a group. Using nearest neighbor linkage and cosine distance, the dendrogram for the data of Section 31.4.1 is presented

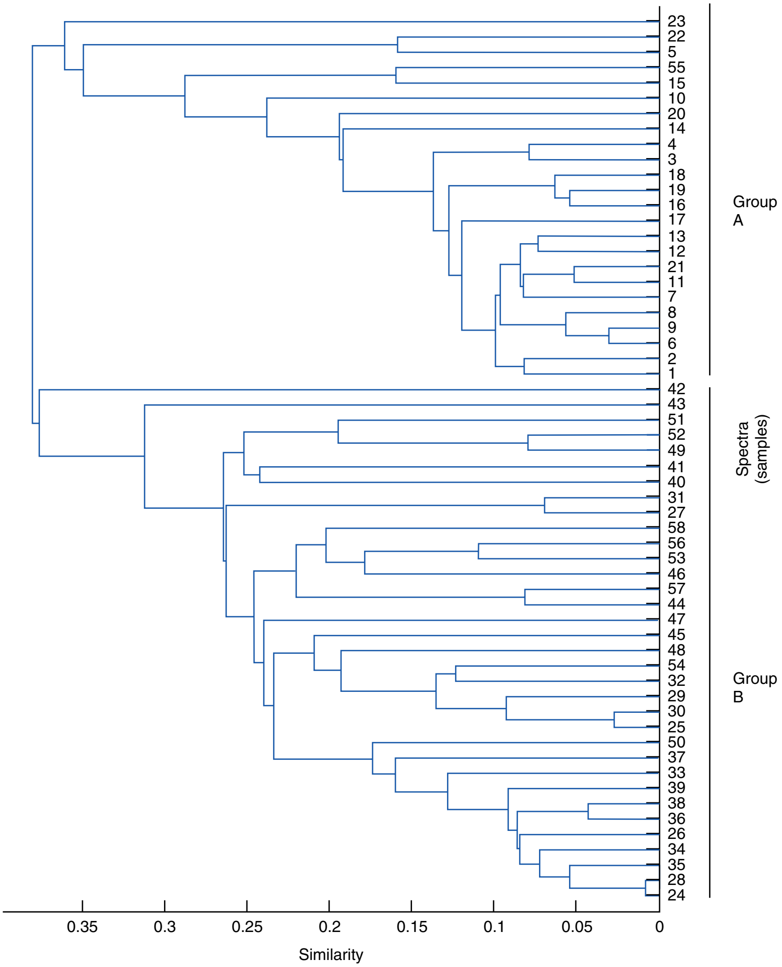

Fig. 31.12 Dendrogram produced by performing cluster analysis on the dataset of Section 31.4.1.

in Figure 31.12. Note that the first group (represented by squares in Figure 31.9) is distinct from the second group. The dendrogram also indicates the samples that are more similar to each other.

Dendrograms do have limitations. There are many clustering methods and each can produce different results. The samples are organized in a linear manner and sometimes the relationships are more complicated and better represented in two or three dimensions. The order of the samples can be variable as it is possible to swap some of the main branches around; hence, parts of the diagram are reflected. However, cluster analysis as described in this section is a well-known and established approach for simplifying and visualizing multivariate data and is often employed in chemometrics.

31.5
Supervised Methods

Classification (often called *supervised pattern recognition*) is at the heart of chemometrics. Can a mid-infrared (MIR) spectrum be used to determine whether a compound is a ketone or an ester? Can the nuclear magnetic resonance spectrum of a tissue sample be used to determine whether a patient is cancerous or not? Can we record the NIR spectrum of an orange juice and decide its origin? Is it possible to monitor a manufacturing process and decide whether the product is acceptable or not? Supervised pattern recognition is used to assign samples to a number of groups (or classes). It differs from exploratory data analysis where, although the relationship between samples is important, there are no predefined groups. There are a very large number of methods for classification and this section summarizes only a few of the most widespread used in chemometrics and spectroscopy; for more comprehensive reviews of methods, see some of the texts referenced in the introduction. However, most common applications in analytical spectroscopy are based on a relatively small number of approaches.

31.5.1
Developing and Assessing Models

Although there are numerous algorithms in the literature, chemometricians have developed a common strategy for developing classification models.

31.5.1.1 Modeling the Training Set

Normally, the first step is to produce a mathematical model between some measurements (e.g., spectra) on a series of objects and their known groups. These objects are called a *training set*. For example, a training set might consist of the NIR spectra of 150 orange juices, 50 known to be from Cyprus, 50 known to be from Spain, and 50 known to be adulterated. Can we produce a mathematical equation that predicts which class an orange juice belongs to from its spectrum? There are several approaches for classification, which are introduced in Sections 31.5.2 – 31.5.4, but the common characteristic is that a model is developed between the spectra and the class each belongs to, which predicts whether a spectrum can be assigned to one class or another.

Once this is done, it is usual to determine how well the model predicts the groups. Table 31.1, often called a

Tab. 31.1 Confusion matrix for classification using a training set.

	Known			Overall
Predicted	**Cyprus**	**Spain**	**Adulterated**	
Cyprus	40	6	6	
Spain	7	44	8	
Adulterated	3	0	36	
Correct	40	44	36	**120**
%CC	80	88	72	**80**

confusion matrix or *contingency table*, illustrates a possible scenario. The higher the relative values down the diagonals, the better the class membership predicted. In this case, of the 150 spectra, 120 are correctly classified. The off-diagonal elements show which class is confused (or mistaken) for another Some classes are modeled better than others, 88% of the Spanish orange juices is correctly classified, but only 72% of the adulterated orange juices. A parameter percentage correctly classified (%CC) can be calculated and is 80% overall. There appears some risk of making a mistake, but the aim of a spectroscopic technique might be to perform screening, and there is a good chance that suspect orange juices (e.g., those adulterated) would be detected, which could then be subject to further detailed analysis. Chemometrics combined with spectroscopy acts like a "sniffer dog" in a customs checkpoint trying to detect drugs. The dog may miss some cases and may even get excited when there are no drugs, but there will be a good chance that the dog is correct. Proof, however, comes only when the suitcase is opened and usually spectroscopy is applied as a cheap and first method, which sifts samples, allowing a smaller number to be examined often by other methods in detail.

Sometimes the number of true positives (TPs), true negatives (TNs), false positives (FPs), and false negatives (FNs) can be computed as an alternative measure of the quality of a classification technique. However, this can be done only for what is called a *one class classifier*, that is, one class against the rest. However, we are interested in knowing whether an orange juice is adulterated or not. Table 31.2 illustrates the way in which such a contingency table can be developed. A "positive" is a spectrum arising from an adulterated orange juice that is known to be adulterated. The percentage of TPs is the percentage of orange juices that are actually positive and the mathematical model predicts to be positive. In the example, the %TP is 72% although the %TN is 97%; hence, the test is quite good at determining whether an orange juice is not adulterated but might miss some adulterated samples.

Tab. 31.2 Stages in developing a 2 × 2 contingency table for determining adulteration.

	Adulterated	**Not adulterated**
Adulterated	36	3
Not adulterated	14	97

	Adulterated	**Not adulterated**
Adulterated	72%	3%
Not adulterated	28%	97%

	Adulterated	**Not adulterated**
Adulterated	TP	FP
Not adulterated	FN	TN

31.5.1.2 Test Sets, Cross Validation, and the Bootstrap

However, it is normal that the training set results in good predictions, but this does not necessarily mean that the method can safely be used in practice. A recommended second step is to test the quality of predictions often using a *test* set. This is a series of samples that has been left out of the original calculations, and is a bit like a "blind test." These samples are assumed to be unknowns at first. Usually the test set predictions are lower than those for the training set, and these are the best indicators as to how well the method can be used in the field. It is particularly important to understand that in spectroscopy it is often possible to obtain several hundreds or thousands of variables per sample. This is a unique property of chemometrics compared to conventional statistics; thus, for the spectroscopist often the sample-to-variable ratio is low, that is, there are many more wavelengths or frequencies than spectra in most typical datasets. In conventional applications of statistics, such as in biology, it is difficult to obtain many measurements per sample. Many classical multivariate methods first reported by biologists were first demonstrated by their application to data obtained by RA Fisher on the iris plant, involving only four variables (Fisher, 1936). However, it can be shown that if the number of variables strongly exceeds the number of samples, it is often possible to get high %CC even starting from completely random datasets (Brereton, 2006); thus, to determine the true effectiveness of the model, it is important to ensure that the model is carefully validated.

Using a test set to determine the quality of predictions is a form of *validation*. The test set could be obtained using samples that are left out of the original dataset. Alternatively, they could have been supplied by an independent laboratory. With modern computers, sometimes it is possible to iteratively generate test sets. For example, if 400 samples are recorded in the original dataset, 100 can be left out randomly at each iteration for testing, and the procedure is repeated many times: computing power increases every year; thus, methods described and implemented 10 years ago can often be improved significantly. What might have taken several hours in 1995 could take a few minutes in 2009 and thus can be repeated many times. With the growth of distributing, computing, and high-performance clusters, we are likely to see significant developments in this direction.

An alternative approach is *cross validation* (Wold, 1978). Only a single training set is required, but usually one (or a group) of the objects is removed at a time, and a model is determined on the remaining samples. Then the prediction on the object (or set of objects) left out is tested. The most common approach is leave one out (LOO) cross validation where one sample is left out at a time. This procedure is repeated until all objects have been left out and is discussed in Section 31.2.3 in the context of PCA. However, the aim in pattern recognition is to determine how well the samples are classified rather than the residual error in modeling the dataset.

Finally, mention should be made of the third alternative called the *bootstrap* (Efron and Tibshirani, 1993). This is a halfway house between cross validation and having a single independent test set and involves iteratively producing several internal test sets: not just removing samples once as in cross validation but also not just having a single test set. A set of samples may be removed, for example, 50 times, each time a different set (although the same samples will usually be part of several of these test sets). The prediction ability each time is calculated, and the overall predictive ability is the average of each iteration.

Naturally, using these it is also possible to calculate the FP or FN rate, and the criterion employed to judge whether a method is suitable or not depends very much on the perspective of the scientist.

If the model is not very satisfactory, there are a number of ways to improve it. The first is to use a different computational algorithm. The second is to modify the existing method – a common approach might involve, for example, instead of using an entire spectrum (many wavelengths are not very meaningful), selecting just the most diagnostic parts of the spectrum. Finally, if everything else fails, change the analytical technique.

It is important to remember that there are two different reasons for using the techniques described in this section. The first is to optimize a computational model. This means that different models can be checked and the one that gives the best prediction rate is retained. In this manner, the samples left out are actually used to improve the model. The second is as an independent test of how well the model performs on unknowns. This is a subtly different reason and sometimes both motivations are mixed up, which can lead to overoptimistic predictions of the quality of a model on unknowns; therefore, care must be taken as discussed by Brereton (2006).

31.5.1.3 **Application**

Once a satisfactory model is available, it can then be applied to unknown samples, using analytical data such as spectra or chromatograms, to make predictions. Usually by this stage, special software is required that is tailor made for a specific application and measurement technique. The software is expected to determine whether a new sample really fits into the training set or not. One major difficulty is the detection of outliers that belong to none of the previously studied groups, for example, if a Brazilian orange juice sample was to be measured when the training set consists just of Spanish and Cypriot orange juices. In areas such as clinical or forensic science, outlier detection can be quite important; otherwise, an incorrect conviction or inaccurate medical diagnosis would be obtained. There are specific protocols according to the application area and type of spectroscopy involved, but outliers and changing instrumental performance are factors that should always be taken into account.

Another problem is to ensure the stability of the method over time, for example, instruments tend to perform slightly differently every day. Sometimes this can have a serious influence on the classification ability of chemometrics algorithms. One way is to perform a small test on the instrument on a regular basis and only accept data if the performance of this test falls within certain limits. If a spectrometer's performance is demonstrably changing with time (as often happens in NIR), and if historic classification (and calibration) models are to be used for future samples, there are special methods called *calibration transfer* that allow adjustments.

31.5.2
Classical Discriminant Analysis

The majority of statistically based software packages contain substantial numbers of procedures, called by various names, such as discriminant analysis, canonical variates analysis, and so on.

31.5.2.1 **Univariate Classification**

The simplest form of classification is *univariate* where one measurement or variable is used to divide objects into groups. An example may be if a peak in an IR spectrum of a known amount of sample is above a certain predefined threshold. If it is, then the sample falls into one group, and if not, it falls into another group. This might be useful, for example, in process analysis, if this peak relates to an unacceptable impurity in the mixture. However, in most problems in the spectroscopy of mixtures, criteria for whether a sample falls into one group or another are more subtle.

31.5.2.2 **Bivariate and Multivariate Discriminant Models**

Often, several measurements are required to determine the group a sample belongs to. Consider performing two measurements, which may involve measuring the intensity of two peaks in a spectrum and producing a graph of the values of these measurements for two groups, as shown in Figure 31.13. The objects denoted by squares are clearly distinct from the objects denoted by circles, but neither of the two measurements, alone, can discriminate between these groups; therefore, both are essential for classification. It is, however, possible to draw a discriminating line between the two groups. Graphically this can be represented by *projecting* the objects onto a line at right angles to this line as demonstrated in Figure 31.14. The projection can now be converted to a position along a single line. Often these numbers are converted to a *class distance*, which is the distance of each object to the center of the classes. If the distance to the center of class A is greater than that to class B, the object is placed in class A and vice versa. It is not always possible to exactly divide the classes into two groups by this method, but the misclassified samples are far from the center of both classes, with the two class distances that are approximately equal.

More sophisticated approaches involve calculating the class centroids (which are the average measurements of all the

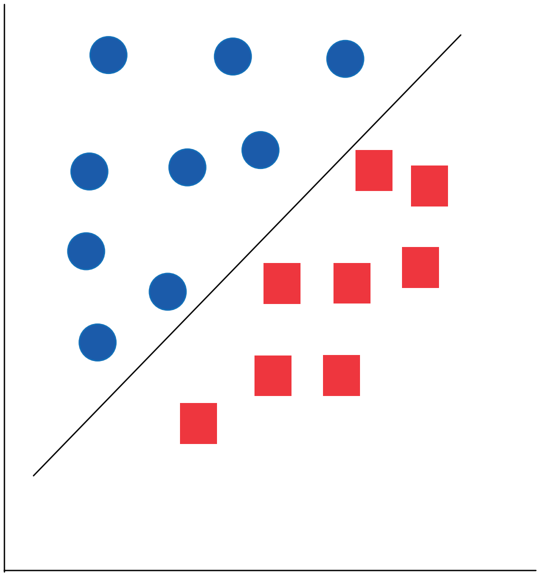

Fig. 31.13 Bivariate example where one measurement is insufficient to distinguish between classes.

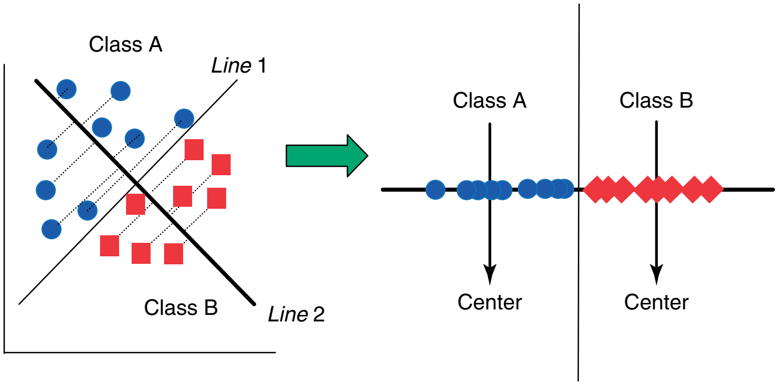

Fig. 31.14 Discriminant function.

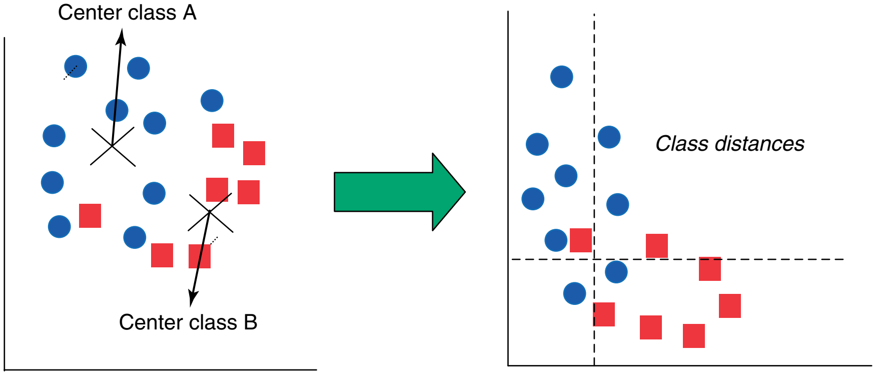

Fig. 31.15 Class distance plot using the Euclidean distance. Top left: almost certainly class A. Bottom left: unambiguous membership. Bottom right: almost certainly class B. Top right: unlikely to be a member of either class, sometimes called an *outlier*.

samples in one class) and the Euclidean distance to the centroids of each class defined as

$$d_A = \sqrt{(\mathbf{x} - \bar{\mathbf{x}}_A)\cdot(\mathbf{x} - \bar{\mathbf{x}}_A)'} \qquad (31.37)$$

where $\mathbf{x}$ is the vector representation of a specific spectrum, preprocessed if necessary, and $\bar{\mathbf{x}}_A$ is the centroid of class A. The distance to two or more class centroids can be calculated. The points no longer fall onto straight lines, but a class distance plot can be obtained as illustrated in Figure 31.15.

It is easy to extend the above-mentioned methods to multivariate situations where instead of two variables many (which can run to several hundreds in spectroscopy) are used to form the raw data. Normally, the class with the smallest distance is taken as the class an object belongs to, but there are several modifications for determining outliers or ambiguous samples or sometimes samples that genuinely belong to more than one class (e.g., a compound might contain both ketone and ester groups and thus exhibit spectroscopic properties of both types of compound and therefore belong to more than one class).

The Euclidean distance is not the only distance measure that can be used; a common enhancement is to employ the Mahalanobis distance defined as

$$d_A = \sqrt{(\mathbf{x} - \bar{\mathbf{x}}_{\mathrm{A}})\cdot\mathbf{S}^{-1}\cdot(\mathbf{x} - \bar{\mathbf{x}}_{\mathrm{A}})'} \quad (31.38)$$

where **S** is a variance–covariance matrix. There are two reasons for this modification to the Euclidean distance.

1. Different classes may be dispersed differently. One class may be quite scattered, whereas another might be very tight. Therefore, a larger Euclidean in from the centroid of the more scattered class has less significance than from the tighter class.
2. Variables may be correlated. This is quite common in spectroscopy, for example, several peaks may arise from a single feature; in NMR of mixtures, each compound will normally result in several features in the spectrum. However, other compounds that could be just as important for the discrimination may have many less spectral features.

A more subtle distinction is between linear discriminant analysis (LDA) and quadratic discriminant analysis (QDA). Both use the Mahalanobis distance, but the former takes the variance–covariance matrix of the entire training set (**S**) and in fact forms linear boundaries between classes, whereas the latter involves using a separate variance–covariance matrix for each class in the training set ($\mathbf{S}_{\mathrm{A}}$) and boundaries between classes can be represented as quadratic terms.

As with all classification models, once it is established on a training set, then it can be tested or applied to other samples as discussed in Section 31.5.1.

31.5.3
Discriminant Partial Least Squares

Another technique that can be employed for classification is discriminant PLS. We have already discussed PLS as a calibration method (Section 31.3.3). In that section we showed how PLS can be used to relate on block of data (e.g., "*x*"), such as a spectrum to another (e.g., "*c*"), such as the concentration of one or more components in a spectrum.

PLS can be used for discriminant analysis or classification (Dixon *et al.*, 2007). The simplest approach is when there are only two classes. In such case, one sets up a "*c*" vector, which consists of a number according to which class a spectrum belongs to; there are two common variations, using "1" and "0" or "+1" and "−1" for classes A and B. We recommend the latter convention, although there is no real difference between either of the approaches. PLS can be used to form a model between the *x* block, for example, a set of spectroscopic measurements, and the *c* block, which may correspond to the origins of the spectra. The results of calibration are a number. A simple rule for interpreting this number may be to assign an object to class A if it is positive and to class B if it is negative. There are elaborations, for example, a large positive or negative number much greater than ±1 might indicate an outlier, and there may be a region around 0 where we feel that the classification is ambiguous; hence, it is possible to choose a different decision threshold. If the two classes are, for example, whether a patient is diseased or not, then the decision threshold can be adjusted to reduce the number of FPs or FNs according to the one that is most important for the specific application.

There are many advantages of using PLS. For example, one can choose the number of significant components using cross validation just as in normal calibration to see how well the data are predicted numerically, or one can determine the optimum number of components by looking at the percent correctly classified. There will be scores, loadings, and weights, and these can be used to provide graphical information on the class structure and about the variables (e.g., spectroscopic wavelengths) that are most diagnostic of each class.

When there are more than two classes involved, the method becomes quite tricky. Normally, there is no particular sequential relationship between the classes. A simple approach is to set up a "*C*" matrix of $N - 1$ columns, where N is the number of classes. For example, if there are three classes, set up the first column with "+1" for class A and "−1" for either classes B or C, and the second column with "+1" for class B and "−1" for classes A or C. It is not necessary to have a third column. Obviously there are several (in this case three) ways of doing this. It can be a bit tricky to interpret the results of classification, but one can use an approach similar to that used in discriminant analysis when there are more than two classes. Alternatively, it is possible to use a "*C*" matrix where each column relates to membership of a single class; hence, for three classes we use three columns, with +1 for members and −1 for nonmembers. One should be careful while interpreting the result of calibration. For example, a negative number may be used to imply that an object does not belong to a specific class. What happens when all the three values from the calibration are negative? Do we say that the object is an outlier and belongs to no class? Or do we find the value closest to "+1" and assign an object to that specific class? There are a variety of ways of making choices and interpreting the results.

31.5.4
K-Nearest Neighbors

The methods discussed in Sections 31.5.2 and 31.5.3 involve producing statistical models. Nearest neighbor methods are conceptually much simpler and do not require elaborate statistical computations, and belong to the class of method often called *machine learning*, which had an influence on chemometric pattern recognition in its early days.

The K-nearest neighbor (KNN) method has been used by chemists for over 30 years (Kowalski and Bender, 1972). The algorithm starts with a number of objects assigned to each class.

The method is implemented as follows.

1. Assign a training set to known classes.
2. Calculate the distance of an unknown to all members of the training set. Usually the multivariate Euclidean distance is computed.
3. Rank these in order (1 = smallest distance and so on).
4. Pick the K smallest distances and see what classes the unknown in closest to.
5. Take the "majority vote" and use this for classification; usually K is an odd

number to prevent the problem of tied votes.

6. Sometimes it is useful to perform KNN analysis for a number of values of K, for example, 3, 5 and 7, and see if the classification changes. This can be used to spot anomalies.

This conceptually simple approach works well in many situations, but it is important to understand the limitations.

The first is that the numbers in each class of the training set should be approximately equal; otherwise, the "votes" will be biased toward the class with most representatives. The second is that for the simplest implementations, each variable is of equal significance. In spectroscopy, we may record hundreds of wavelengths, and some will either not be diagnostic or else be correlated. A way of getting around this is either to select the variables or to use another distance measure. The Mahalanobis distance is quite a useful alternative. The third problem is that ambiguous or outlying samples in the training set can cause major problems in the resultant classification. Fourth, the methods take no account of the spread or variance in a class. For example, if we were trying to determine whether a forensic sample is a forgery, it is likely that the class of forgeries has a much higher variance to the class of nonforged samples.

It is possible to follow procedures of validation (Section 31.5.1.2) just as in all other methods for supervised pattern recognition. There are quite a number of diagnostics that can be obtained using these methods.

However, KNN is a very simple approach that can be easily understood and programmed. Many spectroscopists like these approaches, while statisticians often prefer the more elaborate methods involving modeling the data. KNN makes very few assumptions, whereas methods based on modeling often inherently make assumptions such as normality of noise distributions that are not always experimentally justified, especially when statistical tests are employed to provide probabilities of class membership.

31.6
Multivariate Statistical Process Control

A major trend in chemometrics over the past decade has been in multivariate process control (MSPC) (Kresta, MacGregor and Marlin, 1991). This has its origins in industrial processes. Over the past decade, there has been a large development in online process spectroscopy, especially using miniaturized probes for NIR, MIR, UV/vis, and Raman spectroscopy. This allows real-time monitoring of processes and the ability to take spectra every few minutes if necessary. Some probes can be dipped into a reaction vessel, whereas others are pointed at the reaction mixture. In the pharmaceutical industry in particular, it is important to know whether a product is within accepted limits, and there are often legal requirements that impurities, often byproducts of a reaction and of unknown physiological properties, are below limits. If the composition of a product is outside these limits, then the process may have to be stopped or investigated. Chemometrics combined with online spectroscopy has a major role to play. MSPC can be used to decide whether a process is stable or whether there are unexpected changes. A major driving force has been the process analytical technology (PAT) initiative from the US Food and Drugs Administration (FDA) that has encouraged good practice in process monitoring (US Department of Health and Human Services, 2004).

MSPC has been quite slow to get off the ground and most process engineers still use simple univariate measures. A problem with the conventional univariate approach is that there may be an enormous number of parameters measured in time, at regular intervals; thus, in a typical day hundreds of thousands of pieces of information are available especially if spectroscopy is used for process monitoring. Many of the measurements are related; thus, it makes sense to form a multivariate model rather than several univariate models. Methods such as PCA and PLS come to our rescue. Why plot a single parameter when we could plot the PC (suitably scaled) of several parameters? And why not calibrate spectroscopic data to the concentration of a known additive, and use PLS predictions of concentrations as a variable that is monitored with time? In addition to following a number of physical (or process) measurements, the concentrations of specific compounds can be monitored with time, using multivariate calibration.

More sophisticated multivariate methods can be developed and used by chemical engineers who often first define regions of a reaction or batches of a product as normal operating conditions NOC samples; in the case of a reaction or a product, the samples arise from an acceptable process. These NOC samples represent a series of spectra that are considered normal or acceptable, and the aim of MSPC is to look for samples whose characteristics (normally spectroscopic) deviate significantly from the characteristics of these samples, by calculating a statistic for this deviation. There are two common methods.

1. The D-statistic is a measurement of distance a sample from the process is to the center of the NOC samples using a PC model and determines whether a specific sample has a systematic deviation from the steady state region. Usually the Mahalanobis distance from the NOC class of spectra is computed.
2. The Q-statistic calculates the residuals from the new samples when trying to fit them to a PC model, which is based on the NOC samples. The Q-statistic measures nonsystematic variations, which are not explained by the NOC model.

If both statistics are assumed to follow normal distributions, the control limit for these statistics can be computed; usually 95 and 99% limits are calculated. If samples appear to be exceeding these limits, it is probable that there is some difficulty in the process. It is possible to produce control charts in which the values of these statistics are plotted as a function of process time with the control limits indicated. Ninety-five percent limits are often called *warning limits* and allow the operator to investigate why the process appears to be behaving unusually, although one in 20 of the NOC samples will be expected to exceed these limits. The 99% limit is often called an *action limit.*

The use of chemometrics in online process control is highly developed theoretically and slowly being implemented in certain high-tech industries such as the pharmaceutical and food industries for front line products, but there is still a long way to go; the majority of processes are still monitored using fairly straightforward univariate control charts. Nevertheless, this is a major potential growth area, especially in terms of applications of chemometrics to spectroscopy.

31.7
Conclusions

There is a wide applicability of chemometrics to spectroscopy. With the rapid development of fast online computing power, it is possible to do much more compared to a couple of decades ago. What was feasible only off-line using powerful dedicated mainframes in the 1980s is feasible online and in real time now. Most modern chemometrics approaches had their origins several decades ago, but with user-friendly software, the ability to generate large quantities of data and powerful computing are now available to a wide range of users.

This chapter has reviewed some of the most common chemometrics techniques that have relevance to spectroscopy. There is a much wider ranger of methods, but most spectroscopists come across resolution, calibration, and pattern recognition in their basic work. Many approaches not discussed in this chapter have been developed by the machine learning and statistics community and are only slowly being realized by spectroscopists due to the lack of user-friendly software. PCA- and PLS-based approaches, in contrast, have been incorporated into readily available packages for many years and are now commonplace in some spectroscopies. The next few years are likely to see a rapid development in applications of chemometrics methods to a large variety of spectroscopies. However, most methods are based on a relatively small number of techniques such as MLR, PCA, and PLS, and understanding these basic building blocks will allow the spectroscopist to appreciate other approaches reported in the literature.

Glossary

Agglomerative Clustering: Forming relationships between samples by joining together those that are most similar.

ALS: Alternating least squares – a method of modeling usually spectra and concentration profiles that can incorporate constraints such as positivity.

Bootstrap: Alternative to cross-validation involving an iterative algorithm.

Confusion Matrix: See Contingency Table.

Contingency Table: A table whose rows and columns represent each group in a series of spectra, and containing information about how many samples are classified into each group, allowing misclassification rates to be determined.

Cross-Validation: Method for determining the number of PC or PLS components by leaving some samples out and predicting them.

Dendrogram: Graphic representation of cluster analysis.

Discriminant Analysis: Mathematical approaches for determining grouping in samples.

Dissimilarity Matrix: Like a similarity matrix, except that numerical values relate to dissimilarity.

D-statistic: Indicator used usually in MSPC to determine how close a sample is to the centre of an NOC model.

EFA: Evolving factor analysis – used to look at multivariate processes that evolve.

Eigenvalue: Size of PC.

Euclidean Distance: Difference between two spectra obtained by representing each as a point in multidimensional space.

Factor Analysis: Similar to PCA except that the components have an interpretable meaning, for example, as spectra and concentration profiles.

FN: False negative.

FP: False positive.

Inverse: Defined for most square matrices, for which the product is the unit matrix.

ITTFA: Iterative target transform factor analysis – a method similar to ALS.

KNN: K nearest neighbours – a method for classification.

LDA: Linear discriminant analysis – using Mahalanobis distance calculated on a training set consisting of several groups.

Loadings: Numerical values of PCs corresponding to variables.

Mahalanobis Distance: Difference between two spectra obtained by representing each as a point in multidimensional space and scaling each dimension according to variance.

Matrix: Representation of data in a two-dimensional array.

MLR: Multiple linear regression – an alternative to PLS that relates two sets of data, for example, a series of spectra, to concentrations of constituents.

MSPC: Multivariate statistical process control.

Multivariate: Measurements where there is more than one variable, for example, a spectrum at several wavelengths.

NIPALS: Nonlinear lterative partial least squares – a method for performing PCA.

NOC: Normal operating conditions – used in MSPC to indicate the set of spectra that correspond to samples that are of acceptable quality.

PC: Principal component – characterised by scores and loadings.

PCA: Principal components analysis – exploratory visualisation of data matrices, for example, a series of spectra.

PCR: Principal components regression – alternative to PLS and MLR.

PLS: Partial least squares – method for multivariate calibration of data matrices onto another block, calibrating a series of spectra onto concentrations of constituents.

PLS1: PLS algorithm for which there is a single c variable.

PLS2: PLS algorithm for which there is more than one c variable.

Pseudoinverse: Mathematical equivalent to an inverse for a rectangular matrix.

QDA: Quadratic discriminant analysis – using Mahalanobis distance calculated separately on each group in a training set.

Q-statistic: Indicator used usually in MSPC to determine how well a sample fits an NOC model.

Rectangular Matrix: Matrix for which the number of rows and columns are unequal.

RMSEC: Root mean square error of calibration – used for autopredictive models.

RMSECV: Root mean square error of cross validation – often used to determine how many PLS components are suitable for a model.

RMSEP: Root mean square error of prediction – used on an independent test set.

Rotation: Transforming a PC onto a target vector normally consisting of the concentrations of an analyte.

Sample: A row of a matrix usually representing a spectrum.

Scalar: Single number.

Scores: Numerical values of PCs corresponding to samples.

Similarity Matrix: A matrix whose rows and columns represent samples containing values that indicate how similar each sample is to every other sample.

Square Matrix: Matrix for which the number of rows and columns are equal.

Standardizing: Subtracting the mean and dividing by the standard deviation.

SVD: Singular value decomposition – a method for performing PCA.

Test Set: Samples used to determine how well a model performs on samples left out of the model building.

TN: True negative.

TP: True positive.

Training Set: Samples used to establish a model.

Transformation: See rotation.

Transpose: Swapping rows and columns of a matrix.

Univariate: Measurements where there is single variable.

Validation: Determining how effective a model is.

Variable: A column of a matrix usually representing a frequency or wavelength.

Vector: Representation of data in a one-dimensional array, for example, a column or row of a matrix.

5.1 Introduction

The weak interaction is one of the four known fundamental interactions in nature, the other three being gravity, electromagnetism, and the strong interaction. Unlike gravity and electromagnetism, the weak interaction generates an extremely short-range force between matter, which exponentially vanishes at distances larger than 10^{-18} m. The effect of the weak interaction is thus usually unnoticeable unless one directly probes at a short distance comparable to its range. Because of the uncertainty principle, this requires energies larger than 10^2 GeV, which are attainable only by the highest-energy accelerators at present.

There are low-energy processes, however, in which the weak interaction plays a crucial role. These include decay of most elementary particles, decay of hadrons if stable against the strong and electromagnetic interactions, and β-decay and electron capture of unstable nuclei. Processes involving neutrinos are also due to the weak interaction, since neutrinos have no strong or electromagnetic interactions. Particularly important among these is the nuclear-fusion reaction in stars like the Sun. The main branch of the reaction chain, four protons fusing into a helium-4 nucleus by emitting two positrons and two electron neutrinos, includes processes caused by the weak interaction. The Sun would not shine if the weak interaction did not exist! Moreover, the long lifetime of the Sun, which enabled the evolution of life on the Earth, is the consequence of the weakness of the interaction. The weak interaction, however unfamiliar, is vital to our very existence.

5.2 Elementary Particles

The most basic constituents of matter are called *elementary particles*. Twelve such particles are known to date. Six of them are quarks, named u (up), d (down), s (strange), c (charm), b (bottom), and t (top) quark. Three of the quarks (u, c, t) have electric charge $\frac{2}{3}$ (in units of e) and the others (d, s, b) have charge $-\frac{1}{3}$.

The remaining six elementary particles are leptons. Three of them, e^- (electron), μ^- (muon), and τ^- (tauon or tau), have charge -1. The other three are called *neutrinos* and are electrically neutral: ν_e (electron neutrino), ν_μ (muon neutrino), and ν_τ (tau neutrino). All quarks and leptons have spin (intrinsic angular momentum) $\frac{1}{2}$ in units of h and obey Fermi statistics. Each of them

Encyclopedia of Applied High Energy and Particle Physics. Edited by Reinhard Stock

ISBN: 978-3-527-40691-3

is associated with an antiparticle. Antiparticles have opposite charge to that of the particles and are denoted as $\overline{u}$, $\overline{d}$, $\overline{\nu}_e$, e^+, and so on.

The main differences between the quarks and leptons are that only the former participate in the strong interaction and that each quark has three internal degrees of freedom called *color*, while leptons have no color. These two facts are deeply related to each other. Because of the confining nature of the strong interaction, quarks cannot be observed singly but form color-neutral composite states called *hadrons*. The proton p, neutron n, and pion π are the most familiar hadrons. Hadrons are classified into mesons and baryons. Mesons are integral-spin hadrons (spin 0, 1, ...) and can be viewed as bound states of a quark and an antiquark. Baryons are half-integral-spin hadrons (spin $\frac{1}{2}$, $\frac{3}{2}$, ...) and are composed of three quarks.

The quarks and leptons are grouped into three generations in the order of increasing masses. Atoms and molecules are composed of the first-generation particles u, d, and e. The electron neutrino ν_e is associated with the electron. The second (c, s, ν_μ, μ) and the third (t, b, ν_τ, τ) generations are identical to the first except for the properties related to the mass. We note that the neutrino states are labeled by the corresponding charged leptons (''flavor eigenstates''), as it is the only means we can detect them (see Section 5.10 for neutrino masses).

In addition to these matter particles, four types of elementary particles having spin 1 and obeying Bose statistics are known to exist: γ (photon), g (gluon), W, and Z. These act as mediators of fundamental interactions. The electromagnetic interaction is due to the exchange of a photon, and the strong interaction is caused by gluons. The W and Z bosons are responsible for the weak interaction. These bosons except W are electrically neutral, and each of them is its own antiparticle. The W boson has charge -1, and its antiparticle has charge $+1$. These weak bosons, $W^\pm$ and Z^0, were discovered in 1983 (Arnison *et al.*, 1983a; Banner *et al.*, 1983; Arnison *et al.*, 1983b; Bagnaia, *et al.*, 1983) and had been by far the heaviest elementary particles until the discovery (Abe *et al.*, 1994a; 1994b; 1995; Abachi *et al.*, 1995) of the top quark.

5.3
Elementary Processes of the Weak Interaction

The weak interaction can be divided into two classes, the charged-current and neutral-current interactions. The former is associated with the W boson and the latter with the Z.

All quarks and leptons participate in the weak interaction. Taking the first-generation particles as an example, the elementary processes of charged-current interaction are

$$e^- \longleftrightarrow \nu_e + W^-, \quad d \longleftrightarrow u + W^- \tag{1}$$

and those obtained from Eq. (1) by ''crossing'' (moving a particle to the other side and changing it to its antiparticle). For the first reaction in Eq. (1), the following five processes result from crossing:

$$\begin{aligned} &e^- + \overline{\nu}_e \longleftrightarrow W^-, \quad e^+ + \nu_e \longleftrightarrow W^+ \\ &\nu_e \longleftrightarrow e^- + W^+, \quad \overline{\nu}_e \longleftrightarrow e^+ + W^-, \\ &e^+ \longleftrightarrow \overline{\nu}_e + W^+ \end{aligned} \tag{2}$$

Elementary neutral-current interactions of the first-generation fermions are

$$u \longleftrightarrow u + Z, \quad d \longleftrightarrow d + Z,$$
$$\nu_e \longleftrightarrow \nu_e + Z, \quad e^- \longleftrightarrow e^- + Z \qquad (3)$$

The second and third generations of quarks and leptons interact with the W and Z boson in the same way as the first:

$$\mu^- \longleftrightarrow \nu_\mu + W^-, \quad s \longleftrightarrow c + W^-$$
$$\tau^- \longleftrightarrow \nu_\tau + W^-, \quad b \longleftrightarrow t + W^- \qquad (4)$$

for the charged current, and

$$c \longleftrightarrow c + Z, \quad s \longleftrightarrow s + Z,$$
$$\nu_\mu \longleftrightarrow \nu_\mu + Z \quad \mu^- \longleftrightarrow \mu^- + Z,$$
$$t \longleftrightarrow t + Z, \quad b \longleftrightarrow b + Z,$$
$$\nu_\tau \longleftrightarrow \nu_\tau + Z, \quad \tau^- \longleftrightarrow \tau^- + Z \qquad (5)$$

for the neutral current.

In addition to these couplings within the same generation, intergeneration processes of *quarks* such as

$$s \longleftrightarrow u + W^-, \quad b \longleftrightarrow c + W^- \qquad (6)$$

occur. These have a weaker strength than the processes involving fermions of the same generation. (For leptons, our definition of the neutrino states precludes intergeneration processes.)

Because a fermion changes its identity by emitting or absorbing a W, the charged-current interaction induces instability of most of the quarks and leptons.

No flavor-changing neutral-current interaction such as $s \leftrightarrow d + Z$ has been observed. Because of this diagonality, the neutral-current interaction does not cause decay of particles, and the existence of the neutral-current interaction was demonstrated (Hasert *et al.*, 1973), only after its existence was anticipated by theoretical consideration (Glashow, 1961; Weinberg, 1967; Salam, 1968). By contrast, a process caused by charged-current was already known at the end of the nineteenth century in the form of nuclear β-decays.

Processes creating a W or Z boson have large threshold energies attainable only at very high energy accelerators. At lower energies, second-order processes with a W or Z boson in the intermediate (virtual) state can occur. These include scattering processes such as

$$\nu_\mu + e^- \longrightarrow \left(\mu^- + W^+ + e^-\right)$$
$$\longrightarrow \mu^- + \nu_e \qquad (7)$$

and decay processes such as

$$\mu^- \longrightarrow \left(\nu_\mu + W^-\right) \longrightarrow \nu_\mu + e^- + \nu_e \qquad (8)$$

Before the discovery of the W and Z bosons in 1983, these kinds of processes involving four fermions were the only experimental manifestation of the weak interaction. The amplitude for these processes is suppressed at low energies by a factor of $1/m_W^2$, yielding a very small cross section or decay rate. This is the reason that the weak interaction was named as such, in spite of the fact that its inherent strength is as large as the electromagnetic interaction. This suppression factor can be translated to the range of the weak force, which is of the order of the Compton wavelength of the W boson, $\hbar/m_W c \sim 10^{-18}$ m. This is 8(3) orders of magnitude smaller than the atomic (nuclear) scale.

5.4
Structure of the Weak Interaction

The electromagnetic interaction can be described as the coupling of the electromagnetic field with the electromagnetic current. The current can be described as the bilinear function of quark or lepton fields at the fundamental level. The strength of the interaction is determined by the elementary charge e.

The form of the interaction of W and Z with quarks and leptons is surprisingly similar to the electromagnetic interaction. The W and Z field couple to weak currents, and the interaction can be described by only a small number of parameters, which are the weak-coupling constant g and the weak "charge" of the quarks and leptons. The Z interaction also depends on the electromagnetic coupling e and the electric charge of the particle. In fact, the weak and electromagnetic interactions are deeply entangled with each other.

5.4.1
Charged Current

It is easiest to write the form of the interaction in terms of Lagrangian density. The charged-current interaction is given by

$$\mathcal{L} = -\left(\frac{g}{2\sqrt{2}}\right) J^{\mu} W_{\mu} + \text{Hermitian conjugate} \tag{9}$$

where J^{μ} is the weak charged current,

$$J^{\mu} = \sum_{i,j} V_{ij}\overline{u}_i\gamma^{\mu}(1-\gamma_5)\, d_j + \sum_i \overline{\nu}_i\gamma^{\mu}(1-\gamma_5)\, l_i \tag{10}$$

Here the particles are represented by the corresponding fields: W_{μ} is the W^{+} field, and

$$u_i = (u, c, t)\,, \quad d_i = (d, s, b), \qquad \nu_i = (\nu_e, \nu_{\mu}, \nu_{\tau}), \quad l_i = (e, \mu, \tau) \tag{11}$$

are the Dirac fields for quarks and leptons. The quantity V_{ij} is the element of a 3 × 3 unitary matrix (Kobayashi and Maskawa, 1973) called the *Cabibbo–Kobayashi–Maskawa matrix* or the *quark-mixing matrix*. This matrix represents the mismatch of charge $\frac{2}{3}$ and $-\frac{1}{3}$ quark mass eigenstates and causes the mixing between generations (Gell-Mann and Lévy, 1960; Cabibbo, 1963; Glashow, Iliopoulos and Maiani, 1970; Kobayashi and Maskawa, 1973).

Up to the unitary matrix **V**, each term in Eq. (10) has the same normalization. The strength of the interaction thus is independent of fermion species. This property is called *universality* of the charged-current interaction.

5.4.2
Neutral Current

The neutral-current interaction has the form

$$\mathcal{L} = -g_Z J_Z^{\mu} Z_{\mu} \tag{12}$$

with

$$J_Z^{\mu} = \sum_f \bar{f}\gamma^{\mu}\left(v_f - a_f\gamma_5\right) f \tag{13}$$

where Z^{μ} is the Z field and f is the fermion field (sum over all quarks and leptons is implied). The overall coupling constant g_Z can be written in terms of e and g. For this purpose, it is convenient to define

$$\sin\theta_W = \frac{e}{g} \tag{14}$$

The angle θ_W is called the *Weinberg angle* or the *weak mixing angle*. Then the Z coupling is given by

$$g_Z = \frac{g}{\cos\theta_W} \tag{15}$$

This relation has something to do with the nature of the four bosons $W^{\pm}$, Z, and γ. Originally, there exist a triplet of bosons (W^{+}, W^{0}, W^{-}) and a singlet B^{0}, whose respective coupling constants are g and g'. The γ and Z are the linear combinations of W^{0} and B^{0} with mixing angle θ_W:

$$\gamma = W^{0} \sin\theta_W + B^{0} \cos\theta_W \tag{16}$$

$$Z = W^{0} \cos\theta_W - B^{0} \sin\theta_W \tag{17}$$

The mixing angle is derived from the couplings by the relation $\tan\,\theta_W = g'/g$. The γ and Z coupling constants are

$$\begin{aligned} e &= \frac{gg'}{\sqrt{g^{2}+g'^{2}}} = g\sin\theta_W \\ g_Z &= \frac{g}{\cos\theta_W} = \frac{e}{\cos\theta_W \sin\theta_W} \end{aligned} \tag{18}$$

Vector and axial couplings for each fermion, v_f, a_f, are given by

$$\begin{aligned} v_f = {} & \frac{1}{2}\left[T_3\left(f_L\right) + T_3\left(f_R\right)\right] \\ & -2Q_f \sin^{2}\theta_W \end{aligned} \tag{19}$$

$$a_f = \frac{1}{2}\left[T_3\left(f_L\right) - T_3\left(f_R\right)\right] \tag{20}$$

where Q_f is the electromagnetic charge of the fermion, and $T_3(f_{L,R})$ is the weak charge (called the *third component of weak isospin*) of the left- and right-handed components of the fermion field as given in Table 5.1. The current (Eq. 13) can be cast in the form

$$J^{\mu}_{Z} = J^{\mu}_{3} - J^{\mu}_{\text{em}} \sin^{2}\theta_W \tag{21}$$

Tab. 5.1 Particle content of the standard model.

Fields	**Spin**	**SU(3)**	**SU(2)**	***T*₃**	***Y***	***B***	***L***
$q_L = \begin{pmatrix} u_L \\ d_L \end{pmatrix}$	$\frac{1}{2}$	3	2	$+\frac{1}{2}$ $-\frac{1}{2}$	$+\frac{1}{6}$	$\frac{1}{3}$	0

$H = \begin{pmatrix} H^{0} \\ H^{-} \end{pmatrix}$	0	1	2	$+\frac{1}{2}$ $+\frac{1}{2}$	$-\frac{1}{2}$	0	0

[a] Only the first generation of quarks and leptons is shown. Other generations have identical quantum numbers. H denotes the Higgs field. SU(3) and SU(2) entries show the dimension of the representation, T_3 is the third component of the weak isospin SU(2); Y is the weak hypercharge U(1) quantum number. The electric charge is given by $Q = T_3 + Y$. Baryon number B and lepton number L are shown for convenience, but these are not gauge quantum numbers.

where J^{μ}_{em} is the electromagnetic current and J^{μ}_{3} is the third component of the weak-isospin current. With the charged current and its Hermitian conjugate, J^{μ}_{3} comprises all the three components of weak isospin.

The weak currents (10) and (13) contain both vector (γ_μ) and axial ($\gamma_\mu\gamma_5$) terms, which implies that parity invariance is not respected by these couplings. The parity nonconservation of the weak interaction was conjectured (Lee and Yang, 1956) to explain seemingly contradictory properties of kaons, and immediately confirmed by experiments (Wu *et al.*, 1957; Garwin, Lederman and Weinrich, 1957; Friedman and Telegdi, 1957). The violation of parity invariance in the weak interaction is substantial. The effect is maximal for neutrinos in that only helicity -1 neutrino states participate in the weak interactions. In fact, there is no evidence that helicity $+1$ neutrino states exist.

The weak interaction can thus be described by the parameters e, $\sin^2\theta_W$, and V_{ij}, as well as the W and Z masses m_W and m_Z. Furthermore, the masses satisfy the relation

$$m_Z = \frac{m_W}{\cos\theta_W} \tag{22}$$

5.4.3
Effective Four-Fermion Interaction

At energies sufficiently below the W mass, we can use the following effective Lagrangian to describe the weak interaction. For the charged-current interaction,

$$\mathcal{L}_{\text{eff}} = -\left(\frac{G_F}{\sqrt{2}}\right) J^{\dagger}_{\mu} J^{\mu} \tag{23}$$

where

$$\frac{G_F}{\sqrt{2}} = \frac{g^2}{8m_W^2} \tag{24}$$

is called the *Fermi coupling constant* (the factor of $\sqrt{2}$ is of historical origin). The prototype of this Lagrangian (Fermi, 1934) has been expanded and modified several times before the final form was obtained. Notice that only the ratio of the coupling and W mass appears in this effective interaction.

The corresponding Lagrangian for the neutral current is

$$\mathcal{L}_{\text{eff}} = -2\sqrt{2}G_F J_{Z\mu} J^{\mu}_{Z} \tag{25}$$

with the same overall coupling G_F due to the relation (22).

5.5
Basic Constants of the Weak Interaction

5.5.1
Charged Current

The low-energy charged-current interaction of leptons is governed by only one parameter, G_F. This constant can be determined from the lifetime of the muon and is known with high precision:

$$G_F = 1.16637(1) \times 10^{-5}\,\text{GeV}^2 \tag{26}$$

in natural units (the number in the parenthesis is the error of the last digit).

5.5.2
Flavor Mixing

The charged-current interaction of quarks also depends on the Cabibbo–Kobayashi–Maskawa matrix **V**, which is a 3×3 unitary matrix. Although such a matrix generally has nine independent parameters, not all of them are physically observable because some of the phase degrees of freedom can be absorbed into relative phases of the quark fields. Only four physical parameters remain, three of which are real mixing angles and one is a complex phase. If this phase is nonzero, the charged-current interaction violates CP invariance. The complex phase can appear only when at least three generations of quarks exist. In fact, this was the motivation for Kobayashi and Maskawa in anticipating the existence of six flavors of quarks.

The generation structure of the quarks implies that Cabibbo–Kobayashi–Maskawa matrix is approximately diagonal ($\mathbf{V} \approx 1$) and the intergeneration couplings are suppressed. Furthermore, the off-diagonal elements show some hierarchical structure. Our knowledge of $\mathbf{V}$ is summarized in the following "parameterization" (Wolfenstein, 1983):

$$V = \begin{array}{c} \\ u \\ c \\ t \end{array} \begin{array}{c} \begin{array}{ccc} d & s & b \end{array} \\ \begin{pmatrix} 1-\frac{\lambda^2}{2} & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\frac{\lambda^2}{2} & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1 \end{pmatrix} \end{array} + O(\lambda^4) \tag{27}$$

which is formally an expansion in terms of the parameter $\lambda = V_{\text{us}}$. This and the other three parameters, A, ρ, and η, are determined from the weak interaction processes of hadrons, notably semileptonic decay rates of strange particles and B mesons, as well as CP violating observables:

$$\lambda = 0.2257 \pm 0.0018 \tag{28}$$

$$A = 0.814 \pm 0.022 \tag{29}$$

$$\rho = 0.139^{+0.032}_{-0.016} \tag{30a}$$

$$\eta = 0.358^{+0.015}_{-0.017} \tag{30b}$$

This structure of the matrix has the following phenomenological consequences:

1. suppression of strange-particle decay rates (implying relatively longer lifetimes);
2. stronger suppression of bottom particle decay rates; and
3. that bottom decays preferentially to charmed particles.

The matrix element V_{ud} can be determined from the comparison of muon and nuclear β-decay rates. The result $|V_{\text{ud}}| = 0.97418 \pm 0.00027$, along with the determination of $|V_{\text{us}}|$ and $|V_{\text{ub}}|$ from K and B decays, is compatible with unitarity for three generations,

$$|V_{\text{ud}}|^2 + |V_{\text{us}}|^2 + |V_{\text{ub}}|^2 = 1 \tag{31}$$

5.5.3
Neutral Current

The neutral-current interaction is parameterized by the parameter $\sin^2\theta_W$. This quantity can be extracted from a large number of different neutral-current processes. These measurements give consistent values, which supports the precision of the model. The most precise determination is provided by the studies of Z^0 made at electron–positron colliders LEP and SLC, which produced millions of Z^0 bosons as a resonance between 1989 and 1995, using a number of measurements of angular distribution and polarization asymmetries in the process $e^+e^- \to Z^0 \to \overline{f}f$. An average of these measurements gives

$$\sin^2\theta_W = 0.23119 \pm 0.00014 \tag{32}$$

5.5.4
W and Z Masses

The mass of the Z^0,

$$m_Z = 91.1876 \pm 0.0021\,\text{GeV} \tag{33}$$

is, together with G_F, is the most precisely determined parameter of the weak interaction. The mass of the W boson, $m_W = 80.398 \pm 0.025\,\text{GeV}$, has a larger experimental error. The ratio of the two masses is approximately equal to $(1 - \sin^2\theta_W)^{1/2}$. The slight disagreement arises from the quantum loop effect of the top quark. In fact, the mass of the top quark had been predicted from these measurements before its direct discovery.

5.6
Processes Induced by Weak Interactions

5.6.1
Decay of W and Z

The decay of weak bosons directly reflects their interaction. The charged W^- boson is expected to decay mainly into five modes: $e^-\overline{\nu}_e$, $\mu^-\overline{\nu}_\mu$, $\tau^-\overline{\nu}_\tau$, $d\overline{u}$, and $s\overline{c}$, with the approximate branching ratio of 1 : 1 : 1 : 3 : 3. This results from the universality of charged current, the factor of 3 coming from the three color degrees of freedom of quarks. The partial decay rate for the leptonic mode is calculated to be

$$\Gamma\,(W \longrightarrow e\overline{\nu}) = \frac{G_F m_W^3}{6\sqrt{2}\pi} \tag{34}$$

The measured total width is $\Gamma_W = 2.141 \pm 0.041\,\text{GeV}$.

The neutral weak boson Z^0 decays to any fermion–antifermion pair other than $t\overline{t}$. The decay rate is given by

$$\Gamma\left(Z \longrightarrow \overline{f}f\right) = \frac{NG_F m_W^3}{6\sqrt{2}\pi}\left(v_f^2 + a_f^2\right) \tag{35}$$

where $N = 1$ for leptons and 3 for quarks. The measured branching ratios are approximately 70% for hadrons ($q\overline{q}$ pairs), 20% for invisible final states (neutrino pairs), and 3.4% each for charged-lepton pairs (e^+e^-, $\mu^+\mu^-$, and $\tau^+\tau^-$). The measured total width is $\Gamma_Z = 2.4952 \pm 0.0023\,\text{GeV}$. These widths of W and Z bosons correspond to a lifetime of less than 10^{-24} s. In fact, the weak bosons have the shortest lifetimes we have ever encountered.

5.6.2
Weak Decay of Leptons

The electron, being the lightest charged particle, is absolutely stable. Neutrinos are also stable or at least have an extremely long lifetime. The heavier charged leptons, μ and τ, decay by the weak interaction to their associated neutrino plus a pair of leptons or quarks through a virtual W boson.

5.6.2.1 Muon Decay

The muon decays via the charged-current interaction

$$\mu^- \longrightarrow e^- + \overline{\nu}_e + \nu_\mu \tag{36}$$

The rate of this three-body decay is calculated to be

$$\Gamma\left(\mu \longrightarrow e\overline{\nu}_e\nu_\mu\right) = \frac{G_F^2 m_\mu^5}{192\pi^3} \tag{37}$$

in the approximation of neglecting the electron mass. This m^5 behavior, which can be understood in terms of dimensional analysis (noting that the amplitude is proportional to G_F), is typical of weak three-body decays such as β-decay and decays of charged leptons and heavy quarks (c, b).

The lifetime of muon, $\tau = \hbar/\Gamma \sim 2 \times 10^{-6}$ s, though apparently short, is much longer than the characteristic timescale for the muon, $\hbar/m_\mu c^2 \sim 10^{-23}$ s. This reflects the weakness of the weak interaction at this energy scale. Indeed, the muon lifetime would be of the order of the latter if the decay could be induced by stronginteraction.

5.6.2.2 τ-Decay

The τ-lepton can decay in the same way as the muon:

$$\tau^- \longrightarrow e^- + \overline{\nu}_e + \nu_\tau \tag{38}$$

$$\tau^- \longrightarrow \mu^- + \overline{\nu}_\mu + \nu_\tau \tag{39}$$

In addition, the larger mass of the tau enables semihadronic decays

$$\tau^- \longrightarrow \text{hadrons} + \nu_\tau \tag{40}$$

which at the quark level can be understood as $\tau^- \rightarrow d + \overline{u} + \nu_\tau$ (and a small contribution of $\tau^- \rightarrow \mathrm{s} + \overline{u} + \nu_\tau$). The final hadronic system can be a π^-, $\pi^-\pi^0$, or multimeson states with charge -1.

The partial decay rate for $\tau \rightarrow e\overline{\nu}_e\nu_\tau$ is obtained from Eq. (37) by replacing m_μ by m_τ. The total rate is approximately five times larger (counting two leptonic modes and one semihadronic mode with three colors). The measured leptonic branching fraction $B(\tau \rightarrow e\nu\nu) \sim 18\%$ implies that the hadronic mode is slightly enhanced, an effect of the strong interaction. The lifetime $\tau \sim 3 \times 10^{-13}$ s is much shorter than that of muon, reflecting the difference in mass.

5.6.3
Weak Decay of Hadrons

Hadrons that cannot decay via strong or electromagnetic interactions decay weakly. (The exceptions are the proton and bound neutron, whose decay is forbidden by baryon number conservation.) In general, the states with the lowest mass for a given flavor combination of constituent quarks can decay only by weak interaction. The following is the whole list of weakly decaying mesons, all of which are spin-0 negative-parity particles (their antiparticles are implicit): $\pi^+(u\overline{d})$, $K^+(u\overline{s})$, $K^0(d\overline{s})$, $D^+(c\overline{d})$, $D^0(c\overline{u})$, $D_s^+(c\overline{s})$, $B^+(u\overline{b})$, $B^0(d\overline{b})$, $B_s^0(s\overline{b})$, $B_c^+(c\overline{b})$ (the quark content of each meson is shown in the parentheses). There are also a number of baryons that decays weakly.

5.6.3.1 Neutron and Nuclear β-Decay

The neutron is stable if it is bound into a stable nucleus. However, a free neutron, which is ~1% more massive than a proton, is unstable and decays as

$$n \longrightarrow p + e^- + \overline{\nu}_e \tag{41}$$

with a lifetime of ~10^3 s. This lifetime (much longer than the muon) reflects the small available energy Q in the decay, the rate being proportional to its fifth power.

β-Decays of unstable nuclei are caused by the weak interaction. There are three classes of nuclear β-decays: β^--decay,

Tab. 5.2 Nuclear β-decays.

Category	Reaction	Elementary process
β^--Decay	$(Z, A) \longrightarrow (Z+1, A) + e^- + \overline{\nu}_e$	$n \longrightarrow p + e^- + \overline{\nu}_e$
β^+-Decay	$(Z, A) \longrightarrow (Z-1, A) + e^+ + \nu_e$	$p \longrightarrow n + e^+ + \nu_e$
Electron capture	$(Z, A) + e^- \longrightarrow (Z-1, A) + \nu_e$	$p + e^- \longrightarrow n + \nu_e$

[a] (Z, A) denotes a nucleus with atomic number Z and mass number A, which consists of Z protons and $A - Z$ neutrons.

β^+-decay, and electron capture. All of these are due to the reaction (41) or crossed processes as is summarized in Table 5.2.

In nuclear β-decays, the nucleons can be treated as nonrelativistic. In the nonrelativistic limit, nonvanishing matrix elements arises from the time component of the hadronic vector current (Fermi transition) and the space component of the axial current (Gamow–Teller transition). The former does not change the nuclear spin ($\Delta J = 0$), and the latter has $|\Delta J| = 0, 1$. For example, the decay ${}^{14}_{8}\text{O}(0^+) \rightarrow {}^{14}_{7}\text{N}(0^+)$ (half-life 71 s) is a Fermi transition (spin-parity J^P is shown in parentheses), ${}^{6}_{4}\text{He}(0^+) \rightarrow {}^{7}_{4}\text{Li}(1^+)$ (0.8 s) is a Gamow–Teller transition, and ${}^{3}_{1}\text{H}(\frac{1}{2}^+) \rightarrow {}^{3}_{2}\text{He}(\frac{1}{2}^+)$ (12.3 years) is the mixture of both. Widely varying lifetimes mainly arise from the Q^5 dependence of the rate.

Higher-order and relativistic effects cause “forbidden” transitions with much longer lifetimes. The natural radioactive isotope ${}^{40}_{19}\text{K}$ mainly decays as ${}^{40}_{19}\text{K}(4^-) \rightarrow {}^{40}_{20}\text{Ca}$ with a half-life of 10^9 years. This decay is a third-forbidden transition.

5.6.3.2 **Pion Decay**

Charged pions decay dominantly into a muon and a muon neutrino. The decay rate is

$$\Gamma\left(\pi^+ \longrightarrow \mu^+\nu_\mu\right) = \frac{G_F^2 |V_{\text{ud}}|^2 m_\pi f_\pi^2 m_\mu^2}{8\pi} \times \left(1 - \frac{m_\mu^2}{m_\pi^2}\right)^2 \tag{42}$$

where the pion decay constant f_π is defined by the matrix element for a pion to be created from the vacuum via the charged-current operator (without V_{ud}). From the lifetime of pion, one deduces $f_\pi = 131\,\text{MeV}$. (This quantity is a measure of the size of spontaneous breaking of hadronic chiral symmetry).

Although energetically more preferable, the decay $\pi^+ \rightarrow e^+\nu_e$ is suppressed by a factor $(m_e/m_\mu)^2$, which is the consequence of the current structure of the weak interaction.

5.6.3.3 **Decay of Hadrons Containing Strange Quarks**

The lowest-lying strange mesons decay weakly. The charged kaon K^+ has a lifetime of 1×10^{-8} s. The main decay modes are $\mu^+\nu_\mu$ (64% branching ratio), $\pi^+\pi^0$ (21%), $\pi^+\pi^+\pi^-$ (6%), $\pi^+\pi^0\pi^0$ (2%), $\pi^0\mu^+\nu_\mu$ (3%), and $\pi^0e^+\nu_e$ (5%). The neutral kaon K^0 has two distinct lifetimes as discussed in Section 5.6.5. There are six baryons containing one or more strange quarks (the rest being u or d quarks) that decay weakly. These states are called *hyperons* and all of them have lifetimes in the 10^{-10} s range. For example, the Λ baryon (quark content uds) mainly decays to $p\pi^+$ (64%) and $n\pi^0$ (36%) with a lifetime of 3×10^{-10} s; the Ξ^- baryon (quark content dss) decays to $\Lambda\pi^-$ (lifetime 1.6×10^{-10} s).

5.6.3.4 Decay of Hadrons Containing Heavy Quarks

Weak decay of hadrons containing a charm or bottom quark can be considered in the first approximation as the decay of the heavy quark in the hadron, where the other quarks (spectators) do not play any major role.

Weakly decaying charmed hadrons have lifetimes in the range of 10^{-13}–10^{-12} s. Bottom hadrons have lifetimes of about 1.5×10^{-12} s. The longer lifetime of bottom particles despite the larger mass of b is the consequence of the suppression due to the small Kobayashi–Maskawa matrix element V_{cb}.

5.6.4
Top-Quark Decay

The top quark has an exceptionally large mass of 171.2 ± 2.1 GeV and, unlike other quarks and leptons, can decay to a W boson and to a quark (mostly b). The expected decay width is about 1 GeV. Because of its short lifetime, a top quark produced in a particle collision has no time to form a color-neutral hadron before decaying and no top hadron can practically exist.

5.6.5
Flavor Oscillation: Neutral-Kaon and B-Meson Systems

Neutral flavored mesons such as K^0 and B^0 show an interesting quantum-mechanical phenomenon of particle–antiparticle mixing. The K^0 meson, with its quark content ($d\bar{s}$), is distinct from its antiparticle $\overline{K}^0$ ($s\bar{d}$)). Since the weak interaction can change flavor, transition between these two states is possible at the second order of the effective weak interaction (23). The transition amplitude is large enough that the mixing can occur before the meson decays. Because of this effect, the decay of the produced K^0 does not obey the typical exponential decay law but can be described as the superposition of two exponentially decaying amplitudes corresponding to the following linear combination of K^0 and $\overline{K}^0$ states:

$$|K_S\rangle \sim \frac{1}{\sqrt{2}}\left[(1+\varepsilon)\left|K^0\right\rangle + (1-\varepsilon)\left|\overline{K}^0\right\rangle\right] \tag{43}$$

$$|K_L\rangle \sim \frac{1}{\sqrt{2}}\left[(1+\varepsilon)\left|K^0\right\rangle - (1-\varepsilon)\left|\overline{K}^0\right\rangle\right] \tag{44}$$

Up to the tiny CP-nonconserving effect represented by the parameter ε (see next subsection), the state $K_S(K_L)$ is a CP eigenstate with eigenvalue $+1$ (-1). K_S decays to CP $= +1\, \pi^+\pi^-$ and $\pi^0\pi^0$ states and K_L to CP $= -1 3\pi$ states. These two states have drastically different lifetimes: $\tau(K_S) = 0.9 \times 10^{-10}$ s, $\tau(K_L) = 5 \times 10^{-8}$ s. The oscillation frequency is $1/3.8 \times 10^{-10}\ \mathrm{s}^{-1}$.

Similar mixing is observed in the B^0–$\overline{B}^0$ system, except that the two lifetimes are not very different. On the other hand, only a very small mixing phenomenon is observed for the neutral charmed meson D^0. In fact, the mixing amplitude is expected to be small because of cancellation between s and d intermediate states. Furthermore, the charm decay has no Kobayashi–Maskawa suppression, unlike s or b.

5.6.6
CP-Invariance Violation

Even after the establishment of parity nonconservation in weak interaction, the discovery of the CP-nonconserving decay $K_L \to \pi\pi$ (Christenson *et al.*, 1964) was not anticipated. After this observation, CP-invariance violation was known only in the K^0–$\overline{K}^0$ system for more than three decades until the advent of the B factories. Unlike parity nonconservation, the size of CP violation in kaon decays is very small as it is characterized by the parameter $|\varepsilon| \sim 2 \times 10^{-3}$ in Eqs (43) and (44). In the framework of the Kobayashi–Maskawa scheme, the smallness of the effect can be understood, as it is a higher-order process involving the top quark (the amplitude is proportional to λ^6).

Decays of B mesons are suppressed by a small off-diagonal element of the mixing matrix. This leads to a large CP-nonconserving effect in some decay modes of B mesons, for example, a certain asymmetry between the decays $B \to J/\psi K_S$ and $\overline{B} \to J/\psi K_S$. Study of CP violation in a number of B decay modes at the B factories built at KEK and SLAC confirmed these predictions of the Kobayashi–Maskawa mechanism with a huge amount of B meson data (Abe *et al.*, 2001; Aubert *et al.*, 2001).

5.6.7
Neutrino Interaction

Neutrinos have no strong and electromagnetic interactions and interact only weakly. The cross section of neutrinos with matter is therefore so small that a neutrino can easily penetrate the Earth. The cross section grows as center-of-mass energy squared as long as $E_{\mathrm{c.m.}} < m_W$. For example, the neutrino–nucleon cross section is measured to be $\sigma \sim 0.7 \times 10^{-38} E_\nu\,(\mathrm{GeV})\,\mathrm{cm}^2$ for an incident neutrino energy of E_ν larger than a few giga electronvolts. The neutrino–electron cross section is a few orders of magnitude smaller for the same incident energy.

5.7
Gauge Theory of the Weak Interaction: the Standard Model

The three known fundamental interactions – strong, electromagnetic, and weak – can be very well described by gauge field theory. Gauge theory (Yang and Mills, 1954; Utiyama, 1956; Gell-Mann and Glashow, 1961) is a field theory invariant under gauge transformation. The gauge transformations form a continuous group G (the gauge group) under which the fields transform as representations of the group. Gauge theories are characterized by the invariance under local gauge transformation, the fields at different space-time transforming under different group elements of G: $\phi(x) \to g(x)\phi(x)$, $g \in G$. The theory possesses massless spin-1 bosons called *gauge bosons*, which transform as the adjoint representation of the gauge group. It can also have the spin-$\frac{1}{2}$ and scalar fields in any representation of the gauge group.

The standard model (Glashow, 1961; Weinberg, 1967; Salam, 1968; Glashow, Iliopoulos and Maiani, 1970; Bouchiat, Iliopoulos and Meyer, 1972) is characterized by the gauge group $G = \mathrm{SU}(3) \times \mathrm{SU}(2) \times \mathrm{U}(1)$. Besides the gauge fields, the model contains the fermion fields corresponding to three generations of quarks and leptons and a scalar field called the *Higgs field*. The representation contents of these fields are listed in Table 5.1. Note that the model is chiral, that is, the left- and right-handed fermion fields are in different representations. This is the origin of parity noninvariance of the weak interaction.

The interaction of gauge bosons with every particle in the model is strongly constrained by the gauge symmetry. The interaction is unique once the representation of the particle is fixed. The universality of the gauge interactions is the consequence of this fact.

Gauge symmetry prohibits a mass term for gauge bosons. On the other hand, the weak bosons are massive. This apparent discrepancy can be resolved by the notion of spontaneous symmetry breaking and the Higgs mechanism.

If the lowest energy state (the vacuum) is not invariant under the symmetry of the theory (Lagrangian), the physical spectrum loses the expected manifestation of the symmetry. This situation is called *spontaneous symmetry breaking*. In general, spontaneous breakdown of a continuous symmetry is associated with the appearance of a massless scalar boson, called the *Nambu–Goldstone boson* (Nambu and Jona-Lasinio, 1961; Goldstone, 1961; Goldstone, Salam and Weinberg, 1962). However, if the symmetry is a local gauge symmetry, the gauge boson associated with the symmetry becomes massive and the Nambu–Goldstone boson does not appear in the physical spectrum. This phenomenon is called the *Higgs mechanism* (Englert and Brout, 1964; Higgs, 1964a; 1964b; 1966; Guralnik, Hagen and Kibble, 1964; Kibble, 1967).

In the standard model, the potential for the Higgs field can be constructed such that the Higgs field develops a vacuum expectation value. It breaks the $\mathrm{SU}(2) \times \mathrm{U}(1)_Y$ symmetry down to a subgroup $\mathrm{U}(1)_Q$, a linear combination of $\mathrm{U}(1)_Y$, and one of the generators in $\mathrm{SU}(2)$. Three gauge fields that are associated to the three broken generators become massive, which are $W^\pm$ and Z^0 bosons. The remaining state corresponding to the unbroken group is the massless photon.

The masses of the quarks and leptons also have to be generated by spontaneous symmetry breakdown, since gauge symmetry forbids mass terms for these chiral fermions. In the standard model, fermion-mass generation is accomplished by the Yukawa coupling of the fermion to the Higgs field. The generated mass is proportional to the product of the Yukawa coupling and the Higgs vacuum expectation value.

5.8
The Higgs Boson

In the standard model, one physical scalar particle remains from the Higgs field after spontaneous symmetry breaking. This particle has the same quantum numbers as the vacuum, and its coupling strength to a particle is proportional to the mass of the particle. It thus interacts with electrons and nucleons extremely weakly. Its couplings with the W, Z bosons, and top quark are sizable. The preferred decay modes of the Higgs boson are be to a pair of heaviest possible particles which are energetically allowed, such as $b\bar{b}$, W^+W^-, ZZ, depending on its mass.

The mass of the Higgs boson depends on the self-coupling of the Higgs field and cannot be predicted. At present, there is no evidence for the Higgs boson. The current best lower limit of 114 GeV on its mass is derived from the search for the associated production of a Higgs and a Z^0 boson in e^+e^- annihilation. Within the framework of the minimal standard model, available precision data of the Z boson properties and other weak interaction processes imply that the Higgs boson mass should be smaller than 185 GeV. The forthcoming experiments at the LHC (Large Hadron Collider), a proton–proton collider with a center-of-mass energy of 14 TeV, which is scheduled to start running in 2009, will be able to discover the Higgs particle.

In contrast to the three fundamental interactions, all the electromagnetic, strong, and weak interactions are mediated by spin-1 gauge bosons (may be called *vector-type*), the interactions of the Higgs boson (Yukawa interactions and Higgs self-interactions) are not vector-type and are not governed by gauge symmetry. Discovery of the Higgs boson would thus imply the discovery of a new type of fundamental interactions.

5.9
Origin of Electroweak Symmetry Breaking

Although the standard model gives a consistent description of the three interactions and has passed numerous experimental tests, only the gauge-interaction part has been verified. There is no evidence for or against the existence of the extra forces introduced by the model, namely, the Higgs self-interactions and Yukawa interactions, which are vital to explain the masses of weak bosons and fermions. Theoretically, the model contains as many as 18 parameters, which have to be determined by experiments. Despite being a most economical model, it is unlikely to be the final theory. Generally, two possible directions to replace the standard model have been pursued.

One is a weak-coupling scenario in which the model is viable up to very high energies (typically 10^{16} GeV, the scale of grand unified theories, or the Planck scale 10^{19} GeV, where the gravitational interaction becomes strong). Theories of this type tend to have a problem of naturalness (Susskind, 1979; 't Hooft, 1980; Veltman, 1981) to generate and stabilize the weak scale, which is extremely small compared to the typical scale of the theory. The stability problem is solved if the theory possesses supersymmetry (Wess and Zumino, 1974a; 1974b; Ferrara and Zumino, 1974), which is a symmetry between bosons and fermions.

The supersymmetric version of the standard model contains all particles in the standard model and their superpartners, which have the same quantum numbers except that the spin differs by $\frac{1}{2}$.

(To be precise, the model contains two doublets of Higgs fields.) The model implies the existence of a relatively light neutral Higgs boson with mass $\lesssim$130 GeV. From the naturalness of the theory, the superpartners are expected to have masses of the order of TeV.

The other is a strong-coupling scenario, in which the electroweak symmetry is broken by a strong interaction in the TeV energy region (Weinberg, 1979; Susskind, 1979). No light Higgs boson is expected in this scenario. Instead, W bosons strongly interact at TeV energies, at which new phenomena such as WW resonances are expected. A typical example is the so-called technicolor model. Precision measurements at Z^0 put strong constraints on this scenario (Peskin and Takeuchi, 1990; Peskin and Takeuchi, 1992), and a number of models have already been excluded. This type of symmetry breaking may be realized if the dimension of the space-time is more than four, the extra dimensions being compactified with a scale of 10^{-18} cm (corresponding to TeV scale). The existence of extra dimensions is anticipated in superstring theory, a prime candidate for the unification of all interactions including gravity. In fact, the consistency of the theory requires that the space-time should have exactly 10 dimensions.

Determination of the origin of the symmetry breaking is the most important physical target of particle physics at present. It requires an accelerator, which can reach the energy scale of a TeV or more. The LHC is expected to shed lights on this question with the discovery of the Higgs boson or else. An electron–positron linear colliders in the TeV energy range should further clarify the physics of symmetry breaking with its clean environment.

5.10
Neutrino Masses and Mixing

Experiments that directly tried to measure neutrino masses have yielded negative results. The limit for the electron neutrino mass is $m_{\nu_e} < 2\text{eV}$, which is many orders of magnitude smaller than the masses of the charged leptons and quarks. Limits for the other two are not as strong.

Since neutrinos are neutral, two types of mass are possible: the usual Dirac mass and Majorana mass. A Majorana fermion (fermion with a Majorana mass) is identical to its antiparticle. Although neutrinos are exactly massless in the standard model by construction, neutrino masses arise in various extensions of the standard model. In grand unified theories, a very small Majorana mass can be generated naturally (Gell-Mann, Ramond and Slansky, 1979; Yanagida, 1979).

If neutrinos have Majorana masses, lepton number is not conserved and processes such as neutrinoless double β-decay $(Z,\ A) \rightarrow (Z+2,\ A) + 2e^-$ are allowed. There is no firm observation of such processes, implying that the Majorana mass of the electron neutrino should be less than a few electron volts.

Finite neutrino masses are generally accompanied by the mixing of lepton flavor. The mixing causes a phenomenon called *neutrino oscillation* (Maki, Nakagawa and Sakata, 1962; Gribov and Pontecorvo, 1969). For example, if the electron and muon neutrinos mix with a mixing angle θ to form mass eigenstates ν_1 and ν_2, ν_μ produced by a weakly decaying particle can transform itself into ν_e when it is detected by a reaction with matter. The probability of its occurrence is given (for small neutrino masses) by

$$P(\nu_\mu \longrightarrow \nu_e) = \sin^2 2\theta \sin^2\left(\frac{\Delta m^2 l}{4E}\right) \tag{45}$$

where Δm^2 is the mass-squared difference of the two states, l is the distance traveled by the neutrino between its production and detection, and E is the neutrino energy. Oscillation among three species of neutrinos involves two mass-squared differences and a unitary mixing matrix called *Maki–Nakagawa–Sakata matrix*, which is the lepton counterpart of Cabibbo–Kobayashi–Maskawa matrix and contains three mixing angles and CP violating phase(s).

There has long been indications of this phenomenon in the data of neutrinos from the Sun (solar neutrinos) (Davis, 1994; Hirata *et al.*, 1989; Anselmann *et al.*, 1992a; 1992b; Abdurashitov *et al.*, 1994) and neutrinos from cosmic-ray interactions in the atmosphere (atmospheric neutrinos) (Hirata *et al.*, 1992; Fukuda *et al.*, 1994). New generation experiments have clearly demonstrated that oscillations do occur for both solar (Fukuda *et al.*, 1998a; Ahmad *et al.*, 2002) and atmospheric neutrinos (Fukuda *et al.*, 1998b). Experiments using controlled sources of neutrinos confirmed these findings. These utilize neutrinos from reactors (for the solar neutrino mixing) (Eguchi *et al.*, 2003) and accelerators (for the atmospheric neutrino range) (Ahn *et al.*, 2003; Michael *et al.*, 2006) with a long distance between the source and the detector.

The mass-squared differences and mixing angles associated with the two kinds of oscillations have been measured with accuracy. The atmospheric neutrino oscillation is observed between ν_μ and ν_τ with Δm^2 of 2 to 3×10^{-3} eV^2 and almost one-to-one mixing ($\sin^2 2\theta > 0.92$). The solar neutrino oscillation involves a smaller Δm^2 of $(8.0 \pm 0.3) \times 10^{-5}\,\mathrm{eV}^2$ with $\sin^2 2\theta = 0.86^{+0.03}_{-0.04}$ between ν_e and a mixture of ν_μ and ν_τ.

A characteristic pattern of the neutrino mass-mixing emerges from these measurements. The three mass eigenstates have mass differences of at most 0.05 eV and two of them (ν_1, ν_2) are more closely degenerate within 0.01 eV or less. At present, it is not known either the two close-lying states are lighter (called *normal hierarchy*) or heavier (inverted hierarchy) than ν_3. The lightest state can either be massless or have a finite mass smaller than ~1 eV. Both the measured mixing angles are large. In particular, ν_3 is the nearly equal mixture of ν_μ and ν_τ. A third mixing angle is proportional to the ν_e component in ν_3, for which we have no evidence so far. If this angle is nonzero, a CP violating phase in the neutrino mixing matrix can exist, resulting in a difference in neutrino and antineutrino oscillations. If neutrinos are Majorana fermions, additional CP violation is possible in lepton-number violating processes.

Neutrinos pose further questions to the origin of the masses. Neutrino masses are extremely small. The mixing angles are large, which is in sharp contrast to the quarks. These facts may indicate that the origin of neutrino masses may be different from those of quarks and charged leptons.

5.11
Beyond the Standard Model

New processes which are forbidden or extremely suppressed in the Standard Model are the possible windows for new physics beyond the Standard Model. Just as weak decays have been known long before we can directly study the weak bosons, observation of these processes would indicate the existence of a new physics at very high energies currently inaccessible at direct experiments.

Decays such as $\mu^- \to e^-\gamma$ or $\mu^- \to e^-e^-e^+$ violate lepton-flavor conservation and do not occur in the Standard Model. There is no evidence for such processes so far. Neutrino mass mixing can induce these decays but the effect is far too small to be observed. These processes may occur in models with supersymmetry at a rate observable in experiments in the near future.

Similarly important is the nonconservation of baryon number, which can cause the decay of protons and neutrons bound into the nuclei. Grand unified theories (Georgi and Glashow, 1974) generally predict instability of nucleons (Georgi, Quinn and Weinberg, 1974). The expected lifetime is $\sim 10^{33}$ years in some models, which is within the reach of ongoing experiments.

The electric dipole moment of the neutron d_n, a CP-invariance-violating quantity, has been investigated unsuccessfully. The present limit, $d_n < 3 \times 10^{-26} e$ cm, is consistent with the expectation of the Kobayashi–Maskawa scheme, but gives strong constraints on some other models of CP violation. This quantity, as well as the electric dipole moment of other particles including electron, can provide a clue to new physics.

There are evidences from cosmology that the Standard Model is not the final story. Familiar matter comprises only a small percentage of the energy density of the present universe, the rest being dark matter (one-fourth of the total) and dark energy (three fourths). There are no candidates in the Standard Model capable of explaining them. Inflation, a rapid expansion of the early universe which resulted in the uniformity of the current universe, requires a new field to induce it. Asymmetry of matter and antimatter in the universe necessitates the violation of CP symmetry, but the effect of Kobayashi–Maskawa phase is too small to explain the observed asymmetry. New physics at the tera electronvolt scale such as supersymmetry may answer some of these matters. Energy frontier experiments at the LHC and electron-positron linear colliders can probe hitherto unknown physics directly. On the other hand, precision experiments and searches for new processes at lower energies may reveal new physics at very high energy scale, which cannot be directly probed.

Glossary

Charge Conjugation: Operation that exchanges a particle and its antiparticle. All known interactions except the weak interaction are invariant under change conjugation. (Invariance under charge conjugation means that the Lagrangian does not change its form under the operation.)

CP Invariance: Invariance under a combined operation of charge conjugation and parity. The weak interaction violates CP invariance.

Helicity: Component of spin in the direction of the momentum of a particle. A spin-1/2 fermion has two independent states with helicity ±1/2. Helicity changes its sign under parity transformation.

Natural Units: Unit system with $h = c = 1$. In this system there is only one independent dimension, [mass] = [momentum] = [energy] = 1/[length] = 1/[time].

Parity: Parity means space inversion, changing the sign of all three space coordinates. Strong, electromagnetic, and gravitational interactions are invariant under the parity operation, although the weak interaction is not.

Time Reversal: Operation that changes the sign of time coordinate. According to CPT theorem, invariance under time reversal is equivalent to invariance under CP.

Further Reading

Abers, E.S. and Lee, B.W. (**1973**) Gauge theories, *Phys. Rep.*, **9**, 1–142. An early review of gauge theory, but it has not lost its status as a best account despite limitations due to its age.

Amsler, C. *et al.* (Particle Data Group) (**2008**) Review of particle physics, *Phys. Lett. B*, **667**, 1–1340. Gives a most recent comprehensive summary of elementary-particle data as well as nice short reviews on various subjects of high-energy physics. It is widely used and quoted by particle physicists and is updated every other year. Most of the experimental data in this article are quoted from here.

Cahn, R.N. and Goldhaber, G. (eds) (**1989**) *The Experimental Foundations of Particle Physics*, Cambridge University Press, Cambridge. A nice collection of important original papers on experimental high-energy physics, a large part of which is related to the weak interaction. Also contains extensive introductory writeups.

Cheng, T.-P. and Li, L.-F. (**1984**) *Gauge Theory of Elementary Particle Physics*, Clarendon Press, Oxford. A well-organized textbook on the subject at the graduate level. A companion volume (Problems and Solutions, 2000) is also available.

Georgi, H. (**1984**) *Weak Interactions and Modern Particle Theory*, Benjamin/Cummings, Menlo Park. Gives a concise but very nice and clear account of various aspects of the weak interaction based on gauge theory.

Halzen, F. and Martin, A.D. (**1984**) *Quarks and Leptons: An Introductory Course in Modern Particle Physics*, Wiley, New York. A recommendable undergraduate-level textbook on high-energy physics based on gauge theories.

Marshak, R.E., Riazuddin, and Ryan, C.P. (**1969**) *Theory of Weak Interactions in Particle Physics*, Wiley-Interscience, New York. A treatise on the subject in the pre-gauge-theory area.

Nilles, H.P. (**1984**) Supersymmetry, supergravity and particle physics, *Phys. Rep.*, **110**, 1–162. A standard review on application of super-symmetry to particle physics.

Pais, A. (**1986**) *Inward Bound: Of Matter and Forces in the Physical World*, Clarendon Press, Oxford. Describes the history of high-energy physics since the discovery of x rays in great detail from a professional viewpoint and includes an impressive list of literature.

Peskin, M.E. and Schroeder, D.V. (**1995**) *An Introduction to Quantum Field Theory*, Addison-Wesley, Reading. A very modern textbook on field theory. Unlike most textbooks, the authors put particular emphasis on its connection to physical phenomena.

Weinberg, S. (**1995, 1996, 2000**) *The Quantum Theory of Fields, I, II, III*, Cambridge University Press, Cambridge. A very solid modern textbook on quantum field theory. Volume II treats non-Abelian gauge theories and related concepts that are necessary for the modern understanding of the weak interactions. Volume III is devoted to supersymmetry.
